13

14 **ABSTRACT**

15 The Early Turonian interval represents a unique confluence of climatic and

16 oceanographic conditions including peak surface temperatures, high

17 greenhouse-gas concentrations and maximum Phanerozoic sea level. The

18 susceptibility of this climate mode to astronomical insolation forcing remains

19 poorly understood partly due to a limited time control and unknown phasing of

20 astronomical cycles in this interval. Here we offer a refined astrochronology of

21 the Early Turonian based on laterally consistent precession signals preserved in

22 offshore strata of the Bohemian Cretaceous Basin (central Europe). Pristine

23 amplitude modulation verified through interference patterns in depth-frequency

24 plots provides a robust indication of ~100-kyr and 405-kyr eccentricity phases

25 (maxima and minima) that are pinned to ammonite biozones and new carbon-

26   isotope data from two cores. The Early Turonian is estimated as 885 ±41 (2σ)

27   thousand years (kyr) in duration, with the Cenomanian/Turonian boundary

28   predating the first Turonian 405-kyr maximum (no. 232 in the Geological Time

29   Scale 2020) by 82 ±70 (2σ) kyr. The results support a possible link of the

30   recovery from Oceanic Anoxic Event II to increasing magnitude of seasonal

31   insolation extremes due to rising eccentricity on 405-kyr and million-year (Myr)

32   time scales. Superimposed upon this trend are small-scale carbon-isotope

33   anomalies the pacing of which passes from ∼110 kyr, resembling short

34   eccentricity, to ∼170-kyr, possibly related to obliquity modulation. This

35   eccentricity-to-obliquity transition paralleling the rising phase of Myr-scale

36   eccentricity cycle suggests decoupling of the carbon-cycle perturbations from

37   low-latitude seasonal insolation and involvement of mid- to high-latitude carbon

38   reservoirs.

1. INTRODUCTION

Following a major climatic perturbation related to the Oceanic Anoxic Event II

(OAE II; Schlanger and Jenkyns, 1976), the Early Turonian, ~93-94 million years

(Myr) ago, was an episode of stabilized climate of what is considered the peak

Phanerozoic greenhouse warmth (Clarke and Jenkyns 1999; Friedrich et al.

2012). Both surface temperatures and global sea level reached extreme levels

owing primarily to high rates of ocean-crust production and CO_2 outgassing (e.g.,

Jones and Jenkyns 2001). Compared to OAE II, the carbon-isotope ratios in

marine carbonates and organic matter are enriched in the isotope ^{12}C suggesting

reduced capacity of oceanic and terrestrial organic reservoirs, i.e., improved

recycling of organic carbon that likely contributed to radiative forcing. Short-

term (10^4-year scale) carbon-isotope anomalies with magnitudes 0.2-0.5 ‰ in

both organic and carbonate carbon (Jarvis et al. 2006, 2015; Fig. 1) point to

transient perturbations to the carbon cycle of possible Milankovitch origin (Voigt

et al. 2007). The Early Turonian thus represents an example of peak greenhouse

climate, destabilized on short time scales by external forcings. The potential

astronomical origin represents a testable hypothesis that can be evaluated with

detailed temporal constraints.

Earlier astrochronologies suggested durations of the Early Turonian in

the range of 0.78 to 0.84 Myr (Sageman et al. 2006; Voigt et al. 2008; Tab. 1), but

a substantial (~20%) disagreement exists between these estimates and the

duration provided by the Geological Time Scales (GTS 2012, Ogg and Hinnov

2012; GTS 2020, Gale et al. 2020). More recent studies (Sprovieri et al. 2013;

Eldrett et al. 2015; Batenburg et al. 2016) provided detailed astronomical

63 contexts including the phases of orbital eccentricity, but their

64 chronostratigraphy remains partly controversial (Fig. 1; Tab. 1).

65   In order to test the published results and contribute further details on the

66 temporal framework, we present a new astrochronology based on well-

67 preserved precessional and eccentricity signals in the Bohemian Cretaceous

68 Basin. The results offer a robust interpretation of ~100-kyr, 405-kyr and ~2.4-

69 Myr eccentricity phases that provide new insights into the role of astronomical

70 forcing in carbon-cycle perturbations.

71

72 **2. DEPOSITIONAL SETTING**

73 The Bohemian Cretaceous Basin formed as a continental through shallow-marine

74 siliciclastic system along reactivated, NW-trending faults of the Elbe fault zone

75 (Fig. 2; Uličný et al. 2009). The Cenomanian-Turonian interval is characterized

76 by a basinwide flooding and expansion of hemipelagic carbonates across the

77 basin. The overlying Turonian statigraphy consists predominantly of coarse-

78 grained progradational wedges of deltaic and nearshore siliciclastics (genetic

79 sequences TUR1-3; Uličný et al. 2009) that interfinger distally with offshore to

80 hemipelagic fines (Figs. S1-S6). Astronomical signals are best expressed in distal

81 parts of the siliciclastic depocenter where hemipelagic marlstones and

82 limestones (type A cycles; Figs. 3, S7 and S8) pass upward into offshore through

83 distal prodelta facies with cyclic variations in sand vs. mud contents (highlighted

84 by carbonate cementation; type B cycles; Figs. S7, S8).

85

86 **3. DATA AND METHODS**

87 **3.1. Data**

This study is based on subsurface data. An extensive borehole and well-log database provides a 3-dimensional stratigraphic framework (Uličný et al., 2009, 2014) and makes it possible to (i) trace changes in lithofacies and stratal geometries in the study area to determine the most suitable sites for time series analysis, and (ii) correlate biostratigraphic datums, carbon-isotope events and floating astrochronology across the basin (Figs. S1-S6).

All boreholes examined here exhibit long-term changes in sedimentation rate reflecting progradation of the marginal-marine siliciclastic system and shallowing of the coeval hemipelagic setting. Shorter-term fluctuations in sedimentation rates related to non-deposition and/or erosion across syndepositional faults are documented locally by angular relationships of well-log correlation markers (Figs. S1, S2). Boreholes suitable for time-series analysis and the construction of astronomical age model were selected from the prodeltaic zone based on two criteria: (i) The long-term change in sedimentation rate follows a simple pattern that can be modeled and removed numerically (e.g., linear change in sedimentation rate matched by a reciprocal function of signal wavelength in the depth-frequency plot; Fig. 4b). (ii) Short-term hiatuses and other fluctuations in sedimentation rates are absent or short relative to the tuning targets. The closest fit to these criteria is found in borehole J-719670 located ~5 km offshore from the progradational limit of sequence TUR2 (Fig. 2). Complementary analyses were executed on a series of other boreholes from the along-dip correlation profile. The list of key boreholes, their geographic coordinates and types of data are provided in Table S1.

Time-series analysis (section 3.4) was applied primarily to high-resolution resistivity logs that serve as a proxy for variations in sand/mud ratio

113   and carbonate cementation. The LL7 focused laterolog probe offers a favorable

114   combination of sensitivity to dm- to meter-scale lithological variations in the

115   mixed carbonate-siliciclastic strata, and noise attenuation (gamma-ray logs

116   appear excessively noisy at the dm to meter scales as revealed by comparing

117   closely spaced boreholes). The depth resolution of digitized resistivity logs is 10

118   cm, which in the reference borehole J-719670 corresponds to a minimum of 10

119   samples per the shortest (precessional) cycle discussed in this paper.

120   Isolated core samples from two boreholes (J-703684 and J-854604) and

121   complete cores from boreholes 4523-A Sedlec and 4530-A Horní Beřkovice (Fig.

122   3) were available for a detailed examination of lithology and geochemistry.

123   Greyscale-density profiles for the 4523-A Sedlec core were extracted from high-

124   resolution (~10 pixels/mm) photographs using the image-processing software

125   ImageJ (National Institutes of Health, Bethesda, MD).

126

127   **3.2. Geochemistry**

128   Samples from the 4523-A Sedlec and 4530-A Horní Beřkovice cores were

129   analyzed for carbon-isotope composition of bulk organic carbon ($\delta^{13}C_{org}$). The

130   measurements were performed in the Stable Isotope Laboratory of the

131   Geological Survey, Prague (4523-A), and the Institute of Geochemistry,

132   Mineralogy and Mineral Resources, Charles University, Prague (4530-A).

133   Samples (10-15 g) were pulverized to an analytical-grade powder and

134   decalcified using 10% HCl. Additional details are provided in Text S1. Data are

135   reported relative to the Vienna Peedee Belemnite (VPDB) standard.

136   Reproducibility of duplicate measurements was 0.12 ±0.08 (1σ) ‰ VPDB. The

137 temporal resolution of $\delta^{13}C_{org}$ data from the core 4523-A is 6.7 ±4.6 (1σ) kyr,

138 according to the age model presented here.

139   Major and trace element concentrations were measured with an XRF

140 spectrometer NITON XL3t GOLDD+; the XRF output was calibrated using 10

141 samples analyzed in an accredited laboratory of the Nanotechnology Centre,

142 Technical University of Ostrava.

143

144 **3.3. Chronostratigraphy, biostratigraphy**

145 The Cenomanian/Turonian (C/T) boundary is constrained by a carbon-isotope

146 correlation to the USGS #1 Portland core (Fig. S13) and well-log correlation of

147 the base of ammonite Zone *Watinoceras devonense* from the Pecínov section,

148 indicated there by the occurrence of inoceramid bivalve *Mytiloides puebloensis*

149 (Fig. S4; cf. Košťák et al., 2018). The Lower Turonian ammonite Zone *Mammites*

150 *nodosoides* is delineated by FO *M. nodosoides* at Pecínov (Košťák et al. 2018); a

151 relatively large uncertainty in the correlation FO *M. nodosoides* and *W. devonense*

152 to borehole 4523-A Sedlec (Fig. 3) is due to stratigraphic condensation at

153 Pecínov (Figs. S4 and S13). The base of nannofossil Zone UC 7 which correlates

154 above the base of the *M. nodosoides* Zone (Burnett 1998) is identified at

155 approximately 178.75-181.75 m depth of the core 4523-A (Text S2). The first

156 occurrence of the ammonite *Collignoniceras woollgari* (Mantell), which marks

157 the Lower/Middle Turonian boundary (Ogg and Hinnov 2012), is correlated

158 from borehole Nm-1 (Figs. S5, S6). The base of the Middle Turonian is further

159 confirmed by the Lulworth carbon-isotope excursion (Jarvis et al. 2006; Fig. 1)

160 identified in boreholes 4523-A and 4530-A (Fig. 3).

161

3.4. Time-series analysis and signal processing

Spectral estimates are calculated with the multitaper method (MTM; Thomson 1982) and evolutive harmonic analysis (EHA; Meyers et al. 2001). The statistical significance of the spectral results is quantified using the MTM harmonic F-test (Thomson 1982), and the assignment of spectral maxima to precessional, obliquity and eccentricity terms is verified with the Average Spectral Misfit (ASM; Meyers and Sageman 2007). Frequencies of orbital eccentricity for ASM analysis are estimated from the solutions La2010a through La2010d (Laskar et al. 2011a) following the approach of Malinverno et al. (2010) and Meyers et al. (2012b). Precessional and obliquity frequencies for ASM analysis are adopted from Waltham (2015). All ASM parameters are listed in Tables S2a and S2b. The TimeOpt method (Meyers 2015) is used to verify the correlation between the eccentricity signal and precessional envelope in selected intervals (Figs. S10, S11). All spectral estimates, ASM and TimeOpt calculations are conducted using the R package 'Astrochron', version 0.6 (Meyers, 2014; R Core Team, 2015). Signal filtering is performed with the Matlab script EPNOSE (Laurin et al. 2017) using a modification of the Taner filter (Taner 1992), which is symmetrical on a linear scale (Kodama and Hinnov 2014). Modulation envelopes were extracted with the Hilbert transform in the Matlab Signal Processing Toolbox; the algorithm is based on Marple (1999).

Data preparation included removal of a large-scale linear trend in sedimentation rate. This trend is manifested as a systematic drift in amplitude and F-test significance maxima approximating a reciprocal function of signal wavelength in the frequency domain (Figs. 4b and S9). To remove the linear trend, the depth scale of borehole J-719670 was modified by considering that the

mean spatial period of the precessional cycle evolved linearly from 1/1.05 m at the depth of 403 m to 1/0.32 m at the depth of 368 m (Fig. 4b), and setting this path to a constant value of 1/1.05 m (Fig. 4c). An analogous adjustment is applied to borehole J-650704, where a linear change from the period of 1/1.01 m at the depth of 428 m to the period of 1/0.35 m at the depth of 395 m is tuned to a constant period of 1/1.01 m. The resulting vertical scales are referred to as "detrended depth scales" in this paper (Figs. 4 and 5). Importantly, this type of linear pre-tuning is applied to an interval the time span of which greatly exceeds the period of short-eccentricity cycles (>300 kyr) and therefore should not distort the ~100-kyr modulation patterns examined in this study (section 4.2; cf. Zeeden et al. 2015). In order to reduce variance in the carbonate-rich interval of type A cyclicity, resistivity logs were converted to their common logarithm prior to time-series analysis. Additional details are provided in sections 4.1 through 4.4.

3.5 Astronomical solutions

Precessional and eccentricity signatures identified in this study are compared primarily with the astronomical solution La2010d (Laskar et al. 2011a), because this solution provides the most recent estimate for the precessional index (note that later solutions – Laskar et al. 2011b; Zeebe 2017; Zeebe and Lourens 2019 – are limited to eccentricity). The La2010d reconstructions of precessional index and obliquity have been obtained following the procedure described in Wu et al. (2013). We note, however, that all solutions available to date are unreliable in their prediction of Myr-scale eccentricity modulation beyond ~55 Myr ago (Laskar et al. 2011b; Zeebe 2017; Zeebe and Lourens 2019). No attempt is

212   therefore made in this study to pin the study interval to any particular segment

213   of the astronomical solution. The La2010d series is used primarily as a

214   constraint for the astronomical tuning target and its uncertainty. The solution

215   La2004 (Laskar et al. 2004) is shown for comparison, because, unlike La2010d, it

216   offers compatible eccentricity phases within the bounds of radioisotopic

217   uncertainty (±0.15 Myr, Meyers et al. 2012a) and provides the closes fit to Myr-

218   scale modulation in the Turonian interval (Ma et al. 2019).

219

220   **3.6 Age model**

221   Astrochronology is based on precessional and eccentricity signals identified in

222   the study interval. To estimate the uncertainty related to unstable astronomical

223   solutions, the interpreted precessional cycles are correlated to all segments of

224   the solution La2010d (Laskar et al., 2011a) between 89 and 99 Myr ago that are

225   compatible with eccentricity phasing in the study interval. Interpolation of the

226   age-depth relationships is based on the Bayesian approach and executed with

227   Bchron (Haslett and Parnell 2008). Further details are provided in section 4.4.

228

229   **3.7 Terminology**

230   The term "phasing" is used in this paper to refer to the timing of maxima and

231   minima of astronomical signals. An attempt is made to distinguish the phase of

232   the original astronomical forcing from the phase of filtered lithological or

233   geochemical proxies (through amplitude modulation and interference patterns

234   of precessional signals).

235   In a previous study, Laurin et al. (2016) use the term frequency

236   modulation (FM) to describe systematic changes in the frequency of

10

237   astronomical signals in depth-frequency plots (EHA). Although the EHA patterns

238   discussed here are analogous to Laurin et al.'s FM, a different term – interference

239   patterns (IP) - is used here to avoid confusion with FM examined by other

240   techniques (e.g., Liu et al. 1998; Hinnov 2000).

241

242   **4. RESULTS**

243   **4.1. Astronomical signatures**

244   Spectral estimates and interpretation of astronomical signatures focus on three

245   reference boreholes: J-719670, J-650704, and 4523-A (see Methods; Fig. 3).

246   Borehole J-719670 provides a well-preserved record for most of the Lower

247   Turonian, and is therefore considered the primary reference section. Results for

248   the lower and upper parts of the study interval are refined using data from

249   boreholes 4523-A and J-650704.

250

251   ***4.1.1. Borehole J-719670, resistivity***

252   Spectral estimates for a downhole resistivity log of this borehole show distinct

253   power-spectral and F-test significance maxima in the astronomical band (Fig. 4).

254   Power maxima exceeding the 90% significance level are labelled informally S_1

255   through S_4 and further discussed. A prominent cyclicity starts approximately 5 m

256   beneath the C/T boundary, with most variance located in the frequency band

257    $\sim$0.25 cycle/m ($\sim$4 m period; S_2 in Fig. 4). Approximately 6 m above the C/T

258   boundary, the S_2 signal starts fading and the variance is transferred to higher

259   frequencies, namely S_4. This apparent increase in signal resolution follows

260   decreasing carbonate contents and the onset of siliciclastic-dominated (type B)

261   cyclicity that has a distinct response in the resistivity log. A refined, S_4-scale

262 resolution for the C/T boundary interval is obtained from greyscale data from

263 borehole 4523-A (section 4.1.3).

264   Further up-section, with an increase in siliciclastic contents related to

265 progradation of sequence TUR2, the S_4 trace in EHA plot drifts to lower

266 frequencies consistent with a linear increase in sedimentation rate (reciprocal

267 function of signal wavelength). Removal of the trend (explained in section 3.4

268 and Fig. 4b) makes it possible to examine the detailed structure of the S_4 band;

269 the signal is composed of two separate frequencies (labeled S_{4a} and S_{4b}) whose

270 interference is coherent with the S_2 cyclicity (Figs. 4, 5). ASM analysis (Fig. 4d)

271 suggests that the S_2 and S_4 signals correspond to cycles of orbital eccentricity

272 (97-127 kyr; related to g_4-g_5 and g_4-g_2) and climatic precession (~19–23 kyr),

273 respectively. The S_{4a} and S_{4b} components then correspond to the ~23-kyr (k+g_5

274 and k+g_2) and ~19-kyr (k+g_4 and k+g_3) terms of the precessional index,

275 respectively (where k refers to Earth's precession rate, and g_2 through g_5 are the

276 secular frequencies of planetary motion; Berger and Loutre 1990). A signature of

277 axial obliquity (S_3) is relatively weak and localized; where present, its variance

278 never exceeds variance of the precessional signal (variance ratio <0.7).

279   The EHA patterns (IP in Figs. 4 and 5) suggest well-preserved

280 precessional and eccentricity signals throughout most of the Lower Turonian.

281 Above the Lower/Middle Turonian boundary, however, the astronomical signals

282 become less distinct at the J-719670 site. In addition, the lowermost Turonian of

283 J-719670 exhibits minor condensation spanning marker bed 9 and

284 corresponding to one S_4 (precessional) cycle (Fig. S1). To confirm and refine the

285 estimate of astronomical cyclicity in these intervals, additional boreholes are

286 examined.

287

4.1.2. Borehole J-650704, resistivity

This borehole is located approximately 4 km eastward of J-719670, closer to the

main siliciclastic depocenter of the Turonian depositional system (Fig. 2).

Proximity to the sediment source provides suitable conditions for the extension

of the S_4 signal into the Middle Turonian (Fig. 3). Spectral estimates for the

resistivity log reveal a pattern of S_2 and S_4 cyclicity, which is compatible with the

results for borehole J-719670 (Fig. 5).

4.1.3. Borehole 4523-A, greyscale

Borehole 4523-A Sedlec is located down the depositional dip relative to

boreholes J-719670 and J-650704 (Fig. 2). Type B cyclicity, which consists

primarily of sand/mud alternations (Figs. S7, S8), is less well expressed in this

distal area due to reduced textural variability and local winnowing. However,

unlike resistivity logs of J-719670 and J-650704, the high-resolution greyscale

record of 4323-A makes it possible to resolve the S_4 signal in carbonate-rich

facies surrounding the C/T boundary (Fig. 6).

4.2. Eccentricity phasing

The initial information on the phasing of ~100-kyr and 405-kyr eccentricity

cycles is obtained from bandpassed resistivity logs following removal of a linear

trend in sedimentation rate (Fig. 5). The bandpassed signal, however, does not

reveal the phase relationship between the proxy and the eccentricity forcing. To

estimate the phase, we employ a suit of additional indices including (i) amplitude

modulation of bandpassed precessional signal (see section 4.2.1), and (ii)

312   preservation of interference patterns of the precessional signals in depth-

313   frequency plots. Details on the interpretation are given below.

314

315   ### 4.2.1. Short eccentricity (~100-kyr)

316   The inherent role of orbital eccentricity (e) in determining the impact of axial

317   precession on insolation (quantified by the precessional index, e sinω, where ω is

318   the longitude of the perihelion from the moving equinox) results in an

319   eccentricity-paced modulation of the amplitude of precessional signals (e.g.,

320   Berger and Loutre 1991). This amplitude modulation has therefore been

321   acknowledged as a tool to identify eccentricity maxima and minima (e.g., Herbert

322   1992; Grippo et al. 2004; Zeebe et al. 2017; Laurin et al. 2017). Any signals

323   filtered from geological data are, however, prone to distortion due to

324   sedimentation-rate instabilities and introduction of noise (both natural and

325   analytical) into the filtered bandwidth. An accurate extraction of amplitude-

326   modulated signals from stratigraphic data involves additional challenges such as

327   frequency leakage out of the filtered bandwidth or introduction of harmonic

328   tones into the filtered bandwidth due to short-term fluctuations in accumulation

329   rates, diagenesis or differential compaction. The use of amplitude modulation

330   therefore requires additional support. Here, the integrity of the precessional

331   envelope is evaluated using interference patterns in EHA plot, analogous to the

332   evaluation of 405-kyr phase in a previous study (Laurin et al. 2016).

333   The composition of fundamental frequencies of the main terms of short-

334   eccentricity (g_4-g_2 and g_4-g_5) and precessional index (k+g_5, k+g_2, k+g_4 and k+g_3;

335   Berger and Loutre 1990) links the interference of precessional terms to the

336   eccentricity phase, i.e., (k+g_4)-(k+g_2) = g_4-g_2, and (k+g_4)-(k+g_5) = g_4-g_5. As

337   illustrated in Figure 5c, intervals of constructive interference of the ~19-kyr and

338   ~23-kyr terms mark short-eccentricity maxima, and intervals of destructive

339   interference are aligned with short-eccentricity minima. These patterns can be

340   examined in EHA plots that also make it possible to identify non-stationarities

341   and determine noise levels in the precessional band (see Laurin et al. 2016 for

342   illustration of possible modes of signal distortion and their EHA signatures).

343   In the resistivity log of J-719670, the interference patterns are well

344   preserved between correlation markers 10 and 37 (Fig. 4) suggesting that the

345   precessional signal and its amplitude modulation are not severely distorted in

346   this interval. The precessional envelope in J-719670 can also be extended some

347   distance beneath a minor hiatus near marker bed 9. The J-650704 record is

348   noisier, but exhibits interference patterns that are consistent with those in J-

349   719670 (Fig. 5). The amplitude envelope of S_4 signal in J-719670 is therefore

350   used in this study as the primary tool for the interpretation of short-eccentricity

351   maxima and minima. For intervals lacking a robust precessional modulation,

352   such as the Cenomanian/Turonian boundary interval, the short eccentricity

353   phases are estimated from a filtered S_2 signal, the polarity of which is confirmed

354   with the TimeOpt analysis (Figs. S10 and S11).

355   It should be noted that the above approach cannot resolve minor phase

356   differences and deformations that are to be expected in this depositional setting.

357   However, the method of astrochronological tuning applied here (section 4.4) is

358   not sensitive to minor lead/lag differences in the precessional and eccentricity

359   records; the phasing uncertainty is accommodated by the total uncertainty of the

360   age model.

361

4.2.2. Long eccentricity (405-kyr)

The 405-kyr cycle, the rhythm of which is represented by signal S_1 (Fig. 4d), is part of the same astronomical forcing as the ~100-kyr eccentricity term. The preservation of its phase should therefore be analogous to the preservation of short-eccentricity phase inferred in section 4.2.1. This means that maxima in the filtered resistivity log should *approximate* the maxima in the original signal (as noted above, minor phase uncertainties are accommodated by the tuning approach). If so, then 405-kyr maxima should be located near marker beds 2a, 20 and 36 (Fig. 5). Support for this assumption can be sought in the modulation of precessional and short-eccentricity signals.

As with the short-eccentricity phasing, the phase of 405-kyr eccentricity (g_2-g_5) is involved in the interference of precessional terms. In this case, however, the interpretation in real stratigraphic data would require an exceptionally clear signal permitting separation of the 23.05-kyr $(k+g_5)$ and ~21.81-kyr $(k+g_2)$ precessional terms (Tab. S2a). In spite of an excellent signal preservation, these components cannot be resolved in the study interval. Other indices are therefore required.

Pronounced amplitude modulation and well-developed interference patterns in the precessional band can be expected to form preferably during 405-kyr maxima, as in the theoretical solutions. The nodes in 405-kyr eccentricity, in contrast, should exhibit relatively weak precessional signals and indistinct interference patterns in time-frequency plots (Fig. 5c). Following these assumptions, 405-kyr maxima should be centered between marker beds 17 – 21 and near markers 36 – 37, in agreement with the S_1 bandpass (Fig. 5a,b). This interpretation is further supported by a transient record of eccentricity in the

16

387 Lower/Middle Turonian boundary interval in borehole Bch-1 (central part of the

388 basin; Figs. 7a and S12).

389 Modulation of the short-eccentricity signal (S_2) is of limited use due to an

390 upward decline in its power. Gradual facies change above marker bed 2b (Fig.

391 S7) and local winnowing of marker bed 9 (Fig. 5) also corrupt the S_1 bandpass in

392 the lower part of the study interval. To preserve a realistic, ~1:4 bundling of

393 short-eccentricity vs. long-eccentricity cycles, the lowermost maximum of the

394 405-kyr eccentricity should be located some distance above the lowermost

395 maximum of the S_1 bandpass, between markers 2b and 3 (between short-

396 eccentricity maxima ecc2 and ecc3; Figs. 5 and 7).

397 The final support for the interpretation of 405-kyr phase comes from

398 bundling ratios of short-eccentricity vs. precessional cycles that are controlled

399 chiefly by changes in the instantaneous period of short-eccentricity cycles. The

400 405-kyr minima are typically associated with low instantaneous periods (as low

401 as 77 kyr; Hinnov 2000) and low bundling ratios (as low as 1:3 during ~2.4-Myr

402 nodes). In the study interval, the bundling ratios range from 3.5 to 5.7 with

403 minima near marker beds 7 and 31, coincident with 405-kyr minima predicted

404 by the S_1 bandpass and precessional interference patterns (Fig. 7).

405

406 **4.3. Myr-scale eccentricity**

407 The ~2.4-Myr modulation of orbital eccentricity related to the precession of

408 perihelia of Earth and Mars ($g_4 - g_3$; Laskar et al. 2004) cannot be interpreted

409 directly due to uncertainties in astronomical solutions and a relatively short time

410 span of the study interval (~1 Myr). However, since long-term eccentricity

411 minima exhibit suppressed ~100-kyr modulations (Fig. 5c; cf. Hinnov 2000), the

412 exquisite preservation of ~100-kyr interference patterns in the middle part of

413 the Lower Turonian and lower part of the Middle Turonian makes it possible to

414 infer a broadly defined ~2.4-Myr maximum in this interval. Such a phasing

415 implies a ~2.4-Myr node overlapping with OAE II, in agreement with the results

416 of previous studies (Batenburg et al. 2016; Laurin et al. 2016; Ma et al. 2019).

417

418 **4.4 Age model**

419 The study interval spans twelve short-eccentricity cycles labelled ecc1 through

420 ecc11 (a minor cycle at 405-kyr minimum is labelled ecc3b; Fig. 7). These cycles,

421 combined with the precessional cyclicity, provide the basis for the construction

422 of floating age model. The key issue affecting accuracy of the age estimate is the

423 selection of tuning targets for the eccentricity and precessional signals. A

424 constant tuning target, e.g., 95 kyr for short eccentricity, can be considered

425 inaccurate, because the instantaneous period of this cycle varies significantly in

426 the course of 405-kyr and Myr-scale modulations (e.g., Hinnov 2000). Tuning to a

427 particular segment of an astronomical solution would settle this issue, but all

428 astronomical solutions available to date are unreliable in their prediction of Myr-

429 scale eccentricity modulation beyond ~55 Myr ago (Laskar et al. 2011a,b; Zeebe

430 2017; Zeebe and Lourens 2019). To estimate the uncertainty associated with

431 Myr-scale modulation, we select a 10-Myr interval of the solution La2010d

432 centered at 94 Myr ago (~C/T boundary) and tune the observed signals to every

433 compatible segment of the theoretical solution in this interval.

434   The tuning is performed by linking individual S_4 cycles with precessional

435 cycles of the La2010d solution (Laskar et al. 2011a) within the framework of

436 ~100-kyr (S_2) and 405-kyr (S_1) maxima and minima interpreted in section 4.2. In

18

this concept, the precessional cycles provide the temporal resolution and

eccentricity cycles provide stability (by, for example, identifying missing

precessional beats at eccentricity minima). Each tuning assigns floating ages to

correlation markers 1 through 43, which are manifestations of the precessional

(S_4) cyclicity (Figs. S14 and S15). The mean and standard deviation of the

floating ages, calculated from the total number of tuned segments (n=21),

constitute the nominal age model and uncertainty of the tuning target (Tab. S3).

An interpolation of the nominal age model to chronostratigraphic

boundaries using the Bayesian approach (Haslett and Parnell 2008; Text S3)

suggests an 885 kyr duration for the Early Turonian. The uncertainty of this time

span is estimated as ±41 kyr (95% confidence interval) by combining the

uncertainty of the location of chronostratigraphic boundaries (Fig. 3) and the

uncertainty of the La2010d tuning target (Tab. 2). The age model also quantifies

the timing of eccentricity maxima and minima (Fig. 8): the

Cenomanian/Turonian boundary predates the first Turonian 405-kyr maximum

by 82 ±70 (2σ) kyr, and the Early/Middle Turonian boundary coincides with the

third Turonian 405-kyr maximum within the uncertainty ($2\sigma = 70$ kyr).

4.5 Age-calibrated $\delta^{13}C$

The Bayesian interpolation is further applied to estimate floating ages of carbon-

isotope samples in borehole 4523-A (Fig. 8). This age calibration suggests that

the negative shift in $\delta^{13}C$ following OAE II is superimposed upon increasing 405-

kyr eccentricity. The temporal distribution of small-scale anomalies

approximates a ~110-kyr pacing in the lowermost Turonian, but passes to a

longer, ~170-kyr pattern towards the Middle Turonian (Fig. 8d).

462

5. DISCUSSION

5.1 Chronology of the Early Turonian

The floating-age estimate presented here falls within the range presented in

previous studies (Tab. 1). It is most closely compatible with astrochronology of

the Wunstorf core (Voigt et al. 2008), with which it shares the precession-scale

resolution. The minor difference in the duration of Early Turonian between these

models (<50 kyr) might be related to the selection of monochromatic

precessional tuning target (21 kyr) and the loss of precessional signal in the

uppermost part of the Lower Turonian at Wunstorf. Another robust estimate, the

Portland time scale of Meyers et al. (2001, 2012a) and Sageman et al. (2006),

appears ~100 kyr short compared to the Bohemian model. The difference is

again possibly related to the use of a monochromatic tuning target, in this case

the 95 kyr for short eccentricity in Portland (note that the use of mean short-

eccentricity period of 110 kyr would increase the duration estimate by 16%,

matching the Bohemian estimate within its uncertainty). Other published

astrochronologies are difficult to assess due uncertainties in the definition of

chronostratigraphic boundaries in the Bottaccione (Sprovieri et al. 2013),

Contessa (Batenburg et al. 2016) and Iona (Eldrett et al. 2015) records.

When anchored to the C/T boundary age of 93.9 ±0.15 Myr ago (Meyers

et al. 2012a), the above model gives the age of the Early/Middle Turonian

boundary as 93.02 ±0.16 (2σ) Myr ago. Alternatively, the age of 93.07 ±0.06 (2σ)

Myr ago is obtained by anchoring to 93.95 ±0.05 Myr ago (Jones et al. 2020).

485

5.2 Eccentricity phasing in the Cenomanian–Turonian interval

20

487 The inferred ~2.4-Myr node in eccentricity modulation during OAE II and a long-

488 term increase in the eccentricity amplitudes towards the Middle Turonian are in

489 agreement with previous results supporting the role of increasing seasonality in

490 the recovery from OAE II (Batenburg et al. 2016; Laurin et al. 2016). The 405-kyr

491 phasing, in contrast, cannot be compared directly with previous studies due to

492 uncertainties in stratigraphic correlation to published sections (Figs. 1 and S17)

493 and a lack of direct phase constraints across OAE II. Well-preserved astronomical

494 signals allowing a robust interpretation of the 405-kyr phases have been

495 described from the pre-OAE II interval at Furlo (Batenburg et al. 2016; Laurin et

496 al. 2016). When extrapolating eccentricity cycles of the Bohemian record to the

497 base of OAE II using published astrochronologies (Sageman et al. 2006; Ma et al.

498 2014; Fig. S13), the 405-kyr maxima appear over 90 kyr (>80°) out-of-phase

499 relative to the Furlo record (Fig. 8c). Considering that both the Early Turonian

500 and pre-OAE II eccentricity records are robust, the most likely source of error is

501 in the extrapolation across OAE II. Possible explanations include (i) non-

502 deposition or condensation near the base of Livello Bonarelli at Furlo, (ii) a

503 minor underestimation of the eccentricity target period in the OAE II chronology

504 (see section 5.1), or (iii) potential diachroneity of biostratigraphic markers

505 between the C/T boundary stratotype and Europe (Boulila et al. 2020).

506   Another apparent mismatch is found in the Early Turonian, when

507 comparing the Bohemian 405-kyr record with eccentricity maxima inferred for

508 the Contessa section (Batenburg et al. 2016; Figs. 1f and S17). The two records

509 can, however, be aligned with each other when considering a ±150 kyr

510 uncertainty for the Contessa section (Batenburg et al. 2016) and delineating the

511 Cenomanian/Turonian boundary as in Wendler (2013) (Fig. S17).

512   Using a cosine approximation of the g_2-g_5 metronome (as recommended

513   by Laskar 2020; equation 4.10 in GTS 2020), the earliest Turonian maximum of

514   405-kyr eccentricity corresponds to the cycle no. 232. The results presented here

515   provide a feedback to astronomical solutions by constraining the age of this 405-

516   kyr maximum to 93.87 ±0.09 (2σ) Myr ago, when anchored to the refined C/T

517   boundary age of 93.95 ±0.05 Myr ago (Jones et al. 2020). The eccentricity

518   maximum no. 230, which coincides with the Early/Middle Turonian boundary, is

519   then dated as 93.06 ±0.09 (2σ) Myr ago.

520

521   **5.3 Short-term δ^{13}C anomalies: interbasinal correlation**

522   Comparison with the age-calibrated record of Wunstorf (Voigt et al. 2008)

523   suggests that the most likely candidate for the Holywell CIE is the excursion "se-

524   6" or "se-10". The timing of the Holywell anomaly in the reference section of

525   English Chalk (Jarvis et al. 2006) appears younger even with the updated age of

526   the Early/Middle Turonian boundary (Fig. 8e). Since biostratigraphic arguments

527   for the correlation of Holywell CIE to Münsterland and Lower Saxony have been

528   presented by Voigt et al. (2007, 2008), the mismatch is most likely attributed to

529   the scarcity of age-control points in the English Chalk record and uncertain

530   dating of FO *M. nodosoides* (Fig. 8e).

531   In general, a correlation of small-scale CIEs that lack a distinct structure

532   or magnitude will remain ambiguous without biostratigraphic constraints or

533   detailed age calibration of both the reference section and the correlated section.

534   The original depth-domain profiles and time-domain profiles interpolated across

535   large intervals can provide misleading information about the relative spacing of

536   CIEs due to unrecognized changes in sedimentation rates and distorted age-

537   depth relationships.

538

539   **5.4 Short-term δ¹³C anomalies: timing and origin**

540   The ~100-kyr recurrence interval of short-term $\delta^{13}C$ anomalies in the earliest

541   Turonian (Fig. 8) points to the possible influence of eccentricity-modulated

542   seasonal insolation intensities on the carbon-cycle budget (cf. Berger et al. 1993).

543   The $\delta^{13}C$ signature is, however, not strictly coherent with inferred short-

544   eccentricity cycles (Fig. 6) suggesting a causal mechanism different from that

545   proposed for other greenhouse intervals, e.g., Paleocene-Eocene (Cramer et al.

546   2003; Zeebe et al. 2017). The observed incoherency may point to the

547   heterogeneous composition of carbon sources and sinks, involving sensitivity to

548   different aspects of the insolation control (e.g., seasonal intensity vs. integrated

549   seasonal insolation) and geographic locations. The possible role of high- or mid-

550   latitude carbon reservoirs responding to meridional insolation gradients (cf.

551   Raymo and Nisancioglu 2003) or integrated summer insolation (cf. Huybers

552   2006) is apparent in the transition towards ~170-kyr pacing of $\delta^{13}C$ anomalies in

553   the mid Early Turonian (Fig. 8d). The ~170-kyr term occurs in amplitude

554   modulation of axial obliquity (Hinnov 2000; Fig. S16) and its record in the

555   isotopic balance of the carbon cycle can be amplified by the ~100-kyr residence

556   time of carbon (Kump and Arthur 1999), analogous to the amplification of

557   eccentricity terms from precessional modulation (e.g., Short et al. 1991; Herbert

558   1997).

559   Notably, the transition from short-eccentricity pacing to ~170-kyr pacing

560   is superimposed upon the rising phase of long-term eccentricity modulation

(Figs. 5 and 8b). The loss of eccentricity pacing of $\delta^{13}C$ excursions can therefore not be attributed to the inherent change in eccentricity amplitudes. To produce the observed pattern, the carbon-cycle perturbations must have decoupled from low-latitude seasonal insolation involving carbon storage in the monsoonal belt (cf. Rossignol-Stricks 1983). The main control on carbon-isotope mass balance was transferred to mid- to high-latitudes during this interval, paralleling a Myr-scale, obliquity-paced carbon exchange inferred in previous studies (Wendler et al. 2014; Laurin et al. 2015) and the onset of long-term cooling of surface temperatures (cf. Pucéat et al. 2003; Friedrich et al. 2012).

SUMMARY

1. The record of precessional and eccentricity cycles in the Bohemian Cretaceous Basin constrains the duration of Early Turonian to 885 ±41 (2σ) kyr. Numerical age of the Early/Middle Turonian boundary is 93.07 ±0.06 (2σ) Myr ago (when anchored to C/T boundary age of 93.95 ±0.05 Myr ago; Jones et al. 2020).

2. The Cenomanian/Turonian boundary precedes the first Turonian 405-kyr maximum by 82 ±70 (2σ) kyr. The age of this eccentricity maximum, no. 232 in the metronomic sequence (Laskar 2020), is estimated as 93.87 ±0.09 (2σ) Myr ago (anchored to C/T boundary age of 93.95 ±0.05 Myr ago; Jones et al. 2020).

3. The recovery from OAE II is superimposed upon rising phases of 405-kyr and ~2.4-Myr eccentricity. The ~2.4-Myr cycle peaks between late Early Turonian and early Middle Turonian.

585   4. Astronomical control on the post-OAE II carbon cycle is documented by

586   ~110-kyr pacing of δ^{13}C anomalies, which gives way to ~170-kyr

587   obliquity pattern during the mid Early Turonian. The transition suggests

588   decoupling of the carbon-cycle mass balance from low-latitude seasonal

589   insolation and increasing role of high latitude carbon reservoirs.

Table 1. Comparison of published age estimates for the Early Turonian. CIE = carbon-isotope excursion; n.d. = not defined explicitly.

Table 2. Age calibration of chronostratigraphic boundaries and carbon-isotope excursions (CIE) in reference boreholes.

Figure 1. Overview of chronology (GTS 2012, 2020) and carbon-isotope stratigraphy of the study interval. Major carbon-isotope anomalies (CIEs) are highlighted by blue shading (positive anomalies) and yellow shading (negative anomalies). The Lower/Middle Turonian boundary is defined by the first occurrence (FO) of *Collignoniceras woollgari*, which is penecontemporaneous with the Lulworth CIE (Jarvis et al. 2006). **(a)** English Chalk reference curve; modified after Jarvis et al. (2006); age model after Pearce et al. (2020). **(b)** Borehole Bch-1, Bohemian Cretaceous Basin, interpolated age (Uličný et al. 2014; Jarvis et al. 2015). **(c)** USGS #1 Portland core, Western Interior Basin; lower part (black) after Sageman et al. 2006 ("min option" in their fig. 1); upper part (blue) after Joo and Sageman (2014). **(d)** Wunstorf core, age calibrated (floating astrochronology after Voigt et al. 2008). **(e)** Contessa section plotted in the depth domain (Stoll and Schrag 2000). **(f)** Eccentricity maxima interpreted by Batenburg et al. (2016). Numbers refer to the sequence of cycles in the solution La2011 (Laskar et al. 2011b).

876 **Figure 2.** Paleogeographic context. **(a)** Plate tectonic reconstruction after Hay et

877 al. (1999). Land/sea distribution is simplified after the PALEOMAP Project, C.R.

878 Scotese (www.scotese.com). BCB = the Bohemian Cretaceous Basin. **(b)** Detail of

879 the study area (modified after Uličný et al. 2009, 2014) plotted in the present-

880 day coordinate system.

881

882 **Figure 3.** Reference boreholes and data discussed in this study. Numbers 1a

883 through 46 denote correlation markers (see Figs. S1-S6 for a detailed correlation

884 and Figs. S7-S8 for lithology). Carbon isotope excursions in the Lower Turonian

885 are labelled "se-20", "be-20", etc., where "se" and "be" refer to the location

886 (Sedlec and Beřkovice, respectively). Grey shading highlights the Oceanic Anoxic

887 Event II (OAE II). GR = gamma ray, RES = resistivity, XNN = neutron-neutron log.

888 Blue shading marks the correlation uncertainty of the Cenomanian/Turonian

889 and Lower/Middle Turonian boundaries (Figs. S1-S6 and S13). Type A cycles =

890 carbonate-dominated lithofacies; Type B = siliciclastic-dominated lithofacies

891 (Figs. S7 and S8). Lithostratigraphy after Čech et al. (1980). Genetic sequences

892 after Uličný et al. (2009). Wavy line = omission surface.

893

894 **Figure 4**. Spectral estimates, borehole J-719670. **(a)** Resistivity log (RES). Labels

895 1a through 45 denote correlation markers most of which correspond to maxima

896 in the S_4 signal. **(b)** MTM (3 2π) amplitude estimate for the common logarithm of

897 RES obtained with a 7-m moving window (EHA). F-test significance estimates are

898 presented in Fig. S9. Potential signals are labelled S_1 through S_4. Interference

899 patterns (IP) are highlighted by arches ")". Note that the amplitude and F-test

900 maxima corresponding to the S_4 signal migrate towards lower frequencies

901 paralleling an upward increase in sand contents and a large-scale progradational

902 pattern in the coeval siliciclastic system (Fig. S1). The EHA pattern resembles a

903 reciprocal function of signal wavelength, consistent with a linear increase in

904 sedimentation rate. **(c)** Resistivity log and EHA amplitude after removal of the

905 linear trend. Intervals of constructive interference of S_{4a} and S_{4b} signals (x)

906 delineate ~100-kyr eccentricity maxima. **(d)** MTM and ASM results for the

907 interval 380-418m. The ASM analysis is based on all F-test maxima exceeding the

908 0.90 level between frequencies 0 and 5 cycle/m. Ho/SL = null-hypothesis

909 significance level. Sedimentation rates constrained by GTS 2020 are shown by

910 ochre shading. Blue lines and symbols indicate the best fit to the astronomical

911 terms of long eccentricity (E_1; 405 kyr period), short eccentricity ($E_{2,3}$; 127 and

912 97 kyr periods), obliquity ($O_{1,2}$; 49 and 39 kyr periods) and precession (P_{1-4}; 23 -

913 19 kyr periods; Tab. S2a).

914

915 **Figure 5**. Correlation of astronomical signals. **(a, b)** Astronomical signatures in

916 boreholes J-719670 and J-650704; setup as in Fig. 4. Intervals of constructive

917 interference of the S_{4a} and S_{4b} signals (x) delineate ~100-kyr eccentricity

918 maxima. Series of strong interference patterns (IP) in the EHA plot mark 405-kyr

919 maxima (ochre shading) superimposed upon a maximum in ~2.4-Myr

920 modulation (cf. Fig. 5c). Note that the fidelity of S_4 envelopes and phase of S_1

921 (405-kyr) signals would remain uncertain without IP (cf. Laurin et al. 2016). **(c)**

922 Comparison with the astronomical solution La2010d (Laskar et al. 2011a); the

923 nearest interval compatible with eccentricity phasing in the study interval. Filter

924 setup (Taner, roll-off rate 4×10^4): J-719670, S_4 = 1.00±0.30 cycle/m, S_2 =

925 0.20±0.05 cycle/m, S_1 = 0.05±0.01 cycle/m; J-650704, S_4 = 1.15±0.35 cycle/m, S_2

926   = 0.23±0.05 cycle/m, S_1 = 0.05±0.01 cycle/m; La2010d, prec. = 50±15 cycle/Myr,

927   short ecc. = 10±3 cycle/Myr, long ecc. = 2.47±0.5 cycle/Myr.

928

929   **Figure 6.** Interpretation of astronomical signatures, borehole 4523-A. **(a)**

930   Carbon-isotope data, greyscale and filtered signals. Filter setup (Taner, roll-off

931   rate $4×10^4$): S_4 = 1.00±0.30 cycle/m, S_2 = 0.23±0.05 cycle/m. **(b)** EHA spectral

932   estimate for greyscale data; dashed lines denote the expected trace of the S_4

933   (precessional) signal inferred from correlation to borehole J-719670 (5-m

934   moving average). **(c)** MTM and ASM estimates for greyscale data, interval 190-

935   203 m. See Tables S2a and S2b for ASM setup. Sedimentation rates constrained

936   by GTS 2020 are shown by ochre shading.

937

938   **Figure 7.** Eccentricity framework constraining the tuning target (see also Figs.

939   S14 and S15). **(a-d)** Filtered precessional and eccentricity signals in reference

940   boreholes. Maxima in short-eccentricity cycles (~100 kyr; labelled ecc1 through

941   ecc11) are inferred using a combination of bandpassed S_2 and amplitude

942   envelopes of the precessional signal (S_4): in the middle and upper parts of the

943   succession that exhibit distinct precessional modulations (Fig. 5), the ~100-kyr

944   maxima are based primarily on amplitude envelopes of the S_4 signal in borehole

945   J-719670; the lower part of the succession exhibits less stable precessional

946   signals; ~100-kyr maxima ecc1-ecc3 are therefore placed at maxima in the S_2

947   bandpass (see text). Long-eccentricity, 405-kyr, maxima (ochre shading) are

948   placed at intervals with strong precessional interference patterns (Figs. 4 and 5).

949   **(e)** Bundling ratios of precessional (P) vs. short-eccentricity (E) signals in the

950   study interval. **(f)** Correlation to the nearest compatible segments of the

951 astronomical solutions La2010d (Laskar et al. 2011a) and La2004 (Laskar et al.

952 2004). Filter setup (Taner, roll-off rate 4×10^4): Bch-1, S_2 = 0.15±0.04 cycle/m;

953 4523-A, S_4 = 1.00±0.30 cycle/m, S_2 = 0.23±0.05 cycle/m, S_1 = 0.05±0.01 cycle/m;

954 J-719670, S_4 = 1.00±0.30 cycle/m, S_2 = 0.20±0.05 cycle/m, S_1 = 0.05±0.01

955 cycle/m; J-650704, S_4 = 1.15±0.35 cycle/m, S_2 = 0.23±0.05 cycle/m, S_1 =

956 0.05±0.01 cycle/m; La2004 and La2010d, prec. = 50±15 cycle/Myr, short ecc. =

957 10±3 cycle/Myr, long ecc. = 2.47±0.5 cycle/Myr.

958

959 **Figure 8.** Updated chronology and eccentricity phasing for the Early Turonian.

960 **(a)** Chronology; duration of the Early Turonian is estimated as 885 ±41 kyr (Tab.

961 2); the floating astrochronology is anchored to the C/T boundary, 93.9 ±0.15 Myr

962 ago (Meyers et al. 2012a). Duration of the Cenomanian part of OAE II (shaded) is

963 based on Sageman et al. (2006) and Ma et al. (2014); Fig. S13. **(b)** The nearest

964 segment of the astronomical solution La2010d (Laskar et al. 2011a) whose

965 eccentricity phasing is compatible with eccentricity signatures in the study

966 interval (Figs. 4, 5 and 7). Filter setup as in Figure 7. **(c)** Timing of 405-kyr

967 eccentricity maxima and minima inferred in this study. Numbers refer to the

968 sequence of cycles in the 405-kyr metronome (Laskar 2020). Comparison with

969 eccentricity phasing at Furlo (Italy) is shown at the bottom; IRM = Isothermal

970 Remanent Magnetization; black = sum of eccentricity components; red = 405 kyr

971 (Laurin et al. 2016). **(d)** EHA estimate for age-calibrated $\delta^{13}C_{org}$, borehole 4523-A.

972 **(e)** Age-calibrated carbon-isotope curves. The Early Turonian interval of 4523-A

973 is calibrated in high-resolution as described in sections 4.4 and 4.5. A linear

974 sedimentation rate of 1.55 cm/kyr is applied to the Cenomanian segment of

975 4523-A, beneath marker 1a (grey part of $\delta^{13}C$ curve; Fig. S13). Age calibration of

976 Wunstorf after Voigt et al. (2008), and Portland after Sageman et al. 2006 (black)

977 and Joo and Sageman 2014 (grey). The age model for English Chalk (Jarvis et al.

978 2006; Pearce et al. 2020) has been updated by adjusting the duration of the Early

979 Turonian to 885 kyr; option 1 = Eastbourne and Culver data are interpolated to

980 the GTS2012 age of FO *M.n.* (details in Pearce et al. 2020); option 2 = linear

981 interpolation between C/T boundary and FO *C.w.*, ignoring the GTS age of FO *M.n.*

*) Filtered S_1 is biased due to condensation at ecc3b (Fig. 4) and lithological change (Type A vs. Type B transition; Fig. S7); placing the 405-kyr maximum between
ecc2 and ecc3, i.e., approximately one short-eccentricity cycle above the maximum in filtered S_1 preserves the 1:4 bundling of long- vs. short-eccentricity cycles.

**) Astronomical solutions are aligned vertically to match 405-kyr and Myr-scale phases in the study interval; solution La2010d has been shifted 0.9 Myr towards the
younger end of the time scale, outside of the range of chronostratigraphic uncertainty at the C/T boundary (± 0.15 Myr).

Note: Astronomical solutions constrain periodicities of astronomical terms, but correlation with individual segments serves illustrative purposes only.
The age model and eccentricity phasing inferred here are not based on tuning to any particular segment of astronomical solutions (see text).

*) The nearest segment of La2010d compatible with eccentricity phasing in the study interval (Figs. 5 and 7); to find the nearest fit, the La2010d curve has been shifted 0.9 Myr towards the younger end of the time scale, outside of the range of chronostratigraphic uncertainty (± 0.15 Myr).

Note: Astronomical solutions constrain periodicities of astronomical terms, but correlation with individual segments serves illustrative purposes only. The age model and eccentricity phasing inferred here are not based on tuning to any particular segment of astronomical solutions (see text).

Reference	Location	Duration of Early Turonian [Myr]	Un-certainty [± Myr]	Pros	Cons
Sageman et al. (2006); Meyers et al. (2012a)	Portland	0.785	n.d.	Robust astronomical signature	Short-eccentricity tuning target, monochromatic (95 kyr); modulation of the tuning target not considered
Voigt et al. (2008)	Wunstorf	0.84	n.d.	Precession-scale resolution; robust astronomical signature	Precession-paced chronology does not reach the top of Early Turonian; modulation of the tuning target not considered
GTS 2012 Ogg and Hinnov (2012)		1.0	n.d.		Meyers et al. (2012a) misquoted [1]); Voigt et al. (2008) not considered
Sprovieri et al. (2013)	Bottaccione	0.6-0.8	n.d.	Well-defined 405-kyr signature	No macrofossil zonation; reduced resolution near C/T boundary
Eldrett et al. (2015; their fig. 11)	Iona	1.14	n.d.	High-resolution astronomical signature	No macrofossil zonation; Early/Middle Turonian boundary controversial, placed into a major positive CIE
Batenburg et al. (2016)	Contessa	0.6-1.2	n.d.	Well-defined eccentricity signature	No macrofossil zonation; C/T boundary controversial (cf. Wendler 2013; Fig. 1)
GTS 2020 Gale et al. (2020)		1.0	n.d.		Adopted from GTS 2012 (see above)
This study	Bohemian Cretaceous Basin	0.885	0.041	Precession-scale resolution; robust eccentricity phasing; modulation of the tuning target included	Macrofossil zones correlated from adjacent boreholes (correlation uncertainty acknowledged in the uncertainty range)

[1]) *The duration of W. devonense Zone is given as 0.35 Myr with reference to Meyers et al. (2012a); Meyers et al. (2012a), however, indicate ~0.2 Myr (two short-eccentricity cycles; their figure 1).*
