13

14 **ABSTRACT**

15 The Early Turonian interval represents a unique confluence of climatic and

16 oceanographic conditions including peak surface temperatures, high

17 greenhouse-gas concentrations and maximum Phanerozoic sea level. The

18 susceptibility of this climate mode to short-term forcings such as astronomically

19 paced insolation remains poorly understood partly due to a limited time control

20 and unknown phasing of astronomical cycles in this interval. Here we offer a

21 refined astrochronology of the Early Turonian based on laterally consistent

22 precession signals preserved in offshore strata of the Bohemian Cretaceous

23 Basin (central Europe). Pristine amplitude modulation verified through

24 interference patterns in depth-frequency plots provides a robust indication of

25 ~100-kyr and 405-kyr eccentricity phases (maxima and minima) that are pinned

26   to ammonite biozones and new carbon-isotope data from two cores. The Early

27   Turonian is estimated as 885 ±46 thousand years (kyr) in duration, with the

28   Cenomanian-Turonian boundary predating the nearest 405-kyr maximum by 81

29   ±32 kyr. The results support a possible link of the recovery from Oceanic Anoxic

30   Event II to increasing magnitude of seasonal insolation extremes due to rising

31   eccentricity on 405-kyr and million-year (Myr) time scales. Superimposed upon

32   this trend are small-scale carbon-isotope anomalies the pacing of which passes

33   from ~110 kyr, resembling short eccentricity, to ~170-kyr, possibly related to

34   obliquity modulation. The loss of short-eccentricity pacing despite Myr-scale

35   increase in eccentricity amplitudes suggests decoupling of the carbon-cycle

36   perturbations from low-latitude seasonal insolation and involvement of mid- to

37   high-latitude carbon reservoirs.

1. INTRODUCTION

Following a major climatic perturbation related to the Oceanic Anoxic Event II (OAE II; Schlanger and Jenkyns, 1976), the Early Turonian, ~93-94 million years (Myr) ago, was an episode of stabilized climate of what is considered the peak Phanerozoic greenhouse warmth (Clarke and Jenkyns 1999; Friedrich et al. 2012). Both surface temperatures and global sea level reached extreme levels owing primarily to high rates of ocean-crust production and CO_2 outgassing (e.g., Jones and Jenkyns 2001). Compared to OAE II, the carbon-isotope signature is enriched in the isotope ^{12}C suggesting reduced capacity of oceanic and terrestrial organic reservoirs, i.e., improved recycling of organic carbon that likely contributed to radiative forcing of greenhouse gases. Short-term (10s kyr) carbon-isotope anomalies with magnitudes 0.2-0.5 ‰ in both organic and carbonate carbon (Jarvis et al. 2006, 2015; Fig. 1) point to transient perturbations to the carbon cycle of possible Milankovitch origin (Voigt et al. 2007). The Early Turonian thus represents a rare example of peak greenhouse climate, destabilized on short time scales by external forcings. The potential astronomical origin represents a testable hypothesis that can be evaluated with detailed temporal constraints.

Earlier astrochronologies suggested durations of the Early Turonian in the range of 0.78 to 0.84 Myr (Sageman et al. 2006; Voigt et al. 2008; Tab. 1), but a substantial (~20%) disagreement exists between these estimates and the duration provided by the Geological Time Scale 2012 (GTS2012; Gradstein et al. 2012). More recent studies (Sprovieri et al. 2013; Eldrett et al. 2015; Batenburg et al. 2016) provided detailed astronomical contexts including the phases of

orbital eccentricity, but their chronostratigraphy remains controversial (Fig. 1; Tab. 1).

In order to test the published results and provide additional details that might help to better understand the temporal relationships, we present a new astrochronology based on well-preserved precessional and eccentricity signals in the Bohemian Cretaceous Basin. The results offer a robust interpretation of ~100-kyr, 405-kyr and ~2.4-Myr eccentricity phases that provide new insights into the role of astronomical forcing in carbon-cycle perturbations.

2. DEPOSITIONAL SETTING

The Bohemian Cretaceous Basin formed as a continental through shallow-marine siliciclastic system along reactivated, NW-trending faults of the Elbe fault zone (Fig. 2; Uličný et al. 2009). The Cenomanian-Turonian interval is characterized by a basinwide flooding and expansion of hemipelagic carbonates across the basin. The overlying Turonian statigraphy consists predominantly of coarse-grained progradational wedges of deltaic and nearshore siliciclastics (genetic sequences TUR1-3; Uličný et al. 2009) that interfinger distally with offshore to hemipelagic fines (Figs. S1-S6). Astronomical signals are best expressed in distal parts of the siliciclastic depocenter where hemipelagic marlstones and limestones (type A cycles; Figs. 3, S7 and S8) pass upward into offshore through distal prodelta facies with cyclic variations in sand vs. mud contents (highlighted by carbonate cementation; type B cycles; Figs. S7, S8).

3. DATA AND METHODS

3.1. Data

This study is based on subsurface data. An extensive borehole and well-log

database provides a 3-dimensional stratigraphic framework (Uličný et al., 2009,

2014) and makes it possible to (i) trace changes in lithofacies and stratal

geometries in the study area to determine the most suitable sites for time series

analysis, and (ii) correlate biostratigraphic datums, carbon-isotope events and

floating astrochronology across the basin (Figs. S1-S6).

All boreholes examined here exhibit long-term changes in sedimentation

rate reflecting a long-term progradation of the marginal-marine siliciclastic

system and shallowing of the coeval hemipelagic setting. Shorter-term

fluctuations in sedimentation rates related to non-deposition and/or erosion

across syndepositional faults are documented locally by angular relationships of

well-log correlation markers (Figs. S1, S2). Boreholes suitable for time-series

analysis and the construction of astronomical age model were selected from the

prodeltaic zone based on two criteria: (i) The long-term change in sedimentation

rate follows a simple pattern that can be modeled and removed numerically (e.g.,

linear change in sedimentation rate matched by a reciprocal function of signal

wavelength in the depth-frequency plot; Fig. 4b). (ii) Short-term hiatuses and

other fluctuations in sedimentation rates are absent or short relative to the

tuning targets. The closest fit to these criteria is found in borehole J-719670

located ~5 km offshore from the progradational limit of sequence TUR2 (Fig. 2).

Complementary analyses were executed on a series of other boreholes from the

along-dip correlation profile. The list of key boreholes, their geographic

coordinates and types of data are provided in Table S1.

Time-series analysis (section 3.4) was applied primarily to high-

resolution resistivity logs that serve as a proxy for variations in sand/mud ratio

112 and carbonate cementation. The LL7 focused laterolog probe offers a favorable

113 combination of sensitivity to dm- to meter-scale lithological variations in the

114 mixed carbonate-siliciclastic strata, and noise attenuation (gamma-ray logs

115 appear excessively noisy at the dm to meter scales as revealed by comparing

116 closely spaced boreholes). The depth resolution of digitized resistivity logs is 10

117 cm, which in the reference borehole J-719670 corresponds to a minimum of 10

118 samples per the shortest (precessional) cycle discussed in this paper.

119 Isolated core samples from two boreholes (J-703684 and J-854604) and

120 complete cores from boreholes 4523-A Sedlec and 4530-A Horní Beřkovice (Fig.

121 3) were available for a detailed examination of lithology and geochemistry.

122 Greyscale-density profiles for the 4523-A Sedlec core were extracted from high-

123 resolution (~10 pixels/mm) photographs using the image-processing software

124 ImageJ (National Institutes of Health, Bethesda, MD).

125

126 **3.2. Geochemistry**

127 Samples from the 4523-A Sedlec and 4530-A Horní Beřkovice cores were

128 analyzed for carbon-isotope composition of bulk organic carbon ($\delta^{13}C_{org}$). The

129 measurements were performed in the Stable Isotope Laboratory of the

130 Geological Survey, Prague (4523-A), and the Institute of Geochemistry,

131 Mineralogy and Mineral Resources, Charles University, Prague (4530-A).

132 Samples (10-15 g) were pulverized to an analytical-grade powder and

133 decalcified using 10% HCl. Additional details are provided in Text S1. Data are

134 reported relative to the Vienna Peedee Belemnite (VPDB) standard.

135 Reproducibility of duplicate measurements was 0.12 ±0.08 (1σ) ‰ VPDB. The

136 temporal resolution of $\delta^{13}C_{org}$ data from the core 4523-A is 6.7 ±4.6 (1σ) kyr,

137 according to the age model presented here.

138   Major and trace element concentrations were measured with an XRF

139 spectrometer NITON XL3t GOLDD+; the XRF output was calibrated using 10

140 samples analyzed in an accredited laboratory of the Nanotechnology Centre,

141 Technical University of Ostrava.

142

143 **3.3. Chronostratigraphy, biostratigraphy**

144 The Cenomanian/Turonian (C/T) boundary is constrained by a carbon-isotope

145 correlation to the USGS #1 Portland core (Fig. S13) and well-log correlation of

146 the base of ammonite Zone *Watinoceras devonense* from the Pecínov section,

147 indicated there by the occurrence of inoceramid bivalve *Mytiloides puebloensis*

148 (Fig. S4; cf. Košťák et al., 2018). The Lower Turonian ammonite Zone *Mammites*

149 *nodosoides* is delineated by FO *M. nodosoides* at Pecínov (Košťák et al. 2018); a

150 relatively large uncertainty in the correlation FO *M. nodosoides* and *W. devonense*

151 to borehole 4523-A Sedlec (Fig. 3) is due to stratigraphic condensation at

152 Pecínov (Figs. S4 and S13). The base of nannofossil Zone UC 7 which correlates

153 above the base of the *M. nodosoides* Zone (Burnett 1998) is identified at

154 approximately 178.75-181.75 m depth of the core 4523-A (Text S2). The first

155 occurrence of the ammonite *Collignoniceras woollgari* (Mantell), which marks

156 the Lower/Middle Turonian boundary (Gradstein et al. 2012), is correlated from

157 borehole Nm-1 (Figs. S5, S6). The base of the Middle Turonian is further

158 confirmed by the Lulworth carbon-isotope excursion (Jarvis et al. 2006; Fig. 1)

159 identified in boreholes 4523-A and 4530-A (Fig. 3).

160

3.4. Time-series analysis and signal processing

Spectral estimates are calculated with the multitaper method (MTM; Thomson 1982) and evolutive harmonic analysis (EHA; Meyers et al. 2001). The statistical significance of the spectral results is quantified using the MTM harmonic F-test (Thomson 1982), and the assignment of spectral maxima to precessional, obliquity and eccentricity terms is verified with the Average Spectral Misfit (ASM; Meyers and Sageman 2007). Frequencies of orbital eccentricity for ASM analysis are estimated from the solutions La2010a through La2010d (Laskar et al. 2011a) following the approach of Malinverno et al. (2010) and Meyers et al. (2012b). Precessional and obliquity frequencies for ASM analysis are adopted from Waltham (2015). All ASM parameters are listed in Tables S2a and S2b. The TimeOpt method (Meyers 2015) is used to verify the correlation between the eccentricity signal and precessional envelope in selected intervals (Figs. S10, S11). All spectral estimates, ASM and TimeOpt calculations are conducted using the R package 'Astrochron', version 0.6 (Meyers, 2014; R Core Team, 2015). Signal filtering is performed with the Matlab script EPNOSE (Laurin et al. 2017) using a modification of the Taner filter (Taner 1992), which is symmetrical on a linear scale (Kodama and Hinnov 2014). Modulation envelopes were extracted with the Hilbert transform in the Matlab Signal Processing Toolbox; the algorithm is based on Marple (1999).

Data preparation included removal of a large-scale linear trend in sedimentation rate. This trend is manifested as a systematic drift in amplitude and F-test significance maxima approximating a reciprocal function of signal wavelength in the frequency domain (Figs. 4b and S9). To remove the linear trend, the depth scale of borehole J-719670 was modified by considering that the

186   mean spatial period of the precessional cycle evolved linearly from 1/1.05 m at

187   the depth of 403 m to 1/0.32 m at the depth of 368 m (Fig. 4b), and setting this

188   path to a constant value of 1/1.05 m (Fig. 4c). An analogous adjustment is

189   applied to borehole J-650704, where a linear change from the period of 1/1.01 m

190   at the depth of 428 m to the period of 1/0.35 m at the depth of 395 m is tuned to

191   a constant period of 1/1.01 m. The resulting vertical scales are referred to as

192   "detrended depth scales" in this paper (Figs. 4 and 5). Importantly, this type of

193   linear pre-tuning is applied to an interval the time span of which greatly exceeds

194   the period of short-eccentricity cycles (>300 kyr) and therefore should not

195   distort the ~100-kyr modulation patterns examined in this study (section 4.2; cf.

196   Zeeden et al. 2015). In order to reduce variance in the carbonate-rich interval of

197   type A cyclicity, resistivity logs were converted to their common logarithm prior

198   to time-series analysis. Additional details are provided in sections 4.1 through

199   4.4.

200

201   **3.5 Astronomical solutions**

202   Precessional and eccentricity signatures identified in this study are compared

203   primarily with the astronomical solution La2010d (Laskar et al. 2011a), because

204   this solution provides the most recent estimate for the precessional index (note

205   that later solutions – Laskar et al. 2011b; Zeebe 2017; Zeebe and Lourens 2019 –

206   are limited to eccentricity). The La2010d reconstructions of precessional index

207   and obliquity have been obtained following the procedure described in Wu et al.

208   (2013). We note, however, that all solutions available to date are unreliable in

209   their prediction of Myr-scale eccentricity modulation beyond ~55 Myr ago

210   (Laskar et al. 2011b; Zeebe 2017; Zeebe and Lourens 2019). No attempt is

211 therefore made in this study to pin the study interval to any particular segment

212 of the astronomical solution. The La2010d series is used primarily as a

213 constraint for the astronomical tuning target and its uncertainty. The solution

214 La2004 (Laskar et al. 2004) is shown for comparison, because, unlike La2010d, it

215 offers compatible eccentricity phases within the bounds of radioisotopic

216 uncertainty (±0.15 Myr, Meyers et al. 2012a) and provides the closes fit to Myr-

217 scale modulation in the Turonian interval (Ma et al. 2019).

218

219 **3.6 Age model**

220 Astrochronology is based on precessional and eccentricity signals identified in

221 the study interval. To estimate the uncertainty related to unstable astronomical

222 solutions, the interpreted precessional cycles are correlated to all segments of

223 the solution La2010d (Laskar et al., 2011a) between 89 and 99 Myr ago that are

224 compatible with eccentricity phasing in the study interval. Interpolation of the

225 age-depth relationships is based on the Bayesian approach and executed with

226 Bchron (Haslett and Parnell 2008). Further details are provided in section 4.4.

227

228 **3.7 Terminology**

229 The term "phasing" is used in this paper to refer to the timing of maxima and

230 minima of astronomical signals. An attempt is made to distinguish the phasing of

231 the original astronomical forcing from the phasing of filtered lithological or

232 geochemical proxies of the astronomical forcing (through amplitude modulation

233 and interference patterns of precessional signals).

234   In a previous study, Laurin et al. (2016) use the term frequency

235 modulation (FM) to describe systematic changes in the frequency of

astronomical signals in depth-frequency plots (EHA). Although the EHA patterns

discussed here are analogous to Laurin et al.'s FM, a different term – interference

patterns (IP) - is used here to avoid confusion with FM examined by other

techniques (e.g., Liu et al. 1998; Hinnov 2000).

4. RESULTS

4.1. Astronomical signatures

Spectral estimates and interpretation of astronomical signatures focus on three

reference boreholes: J-719670, J-650704, and 4523-A (see Methods; Fig. 3).

Borehole J-719670 provides a well-preserved record for most of the Lower

Turonian, and is therefore considered the primary reference section. Results for

the lower and upper parts of the study interval are refined using data from

boreholes 4523-A and J-650704.

4.1.1. Borehole J-719670, resistivity

Spectral estimates for a downhole resistivity log of this borehole show distinct

power-spectral and F-test significance maxima in the astronomical band (Fig. 4).

Power maxima exceeding the 90% significance level are labelled informally S_1

through S_4 and further discussed. A prominent cyclicity starts approximately 5 m

beneath the C/T boundary, with most variance located in the frequency band

$\sim$0.25 cycle/m ($\sim$4 m period; S_2 in Fig. 4). Approximately 6 m above the C/T

boundary, the S_2 signal starts fading and the variance is transferred to higher

frequencies, namely S_4. This apparent increase in signal resolution follows

decreasing carbonate contents and the onset of siliciclastic-dominated (type B)

cyclicity that has a distinct response in the resistivity log. A refined, S_4-scale

261   resolution for the C/T boundary interval is obtained from greyscale data from

262   borehole 4523-A (section 4.1.3).

263   Further up-section, with an increase in siliciclastic contents related to

264   progradation of sequence TUR2, the S_4 trace in EHA plot drifts to lower

265   frequencies consistent with a linear increase in sedimentation rate (reciprocal

266   function of signal wavelength). Removal of the trend (explained in section 3.4

267   and Fig. 4b) makes it possible to examine the detailed structure of the S_4 band;

268   the signal is composed of two separate frequencies (labeled S_{4a} and S_{4b}) whose

269   interference is coherent with the S_2 cyclicity (Figs. 4, 5). ASM analysis (Fig. 4d)

270   suggests that the S_2 and S_4 signals correspond to cycles of orbital eccentricity

271   (97-127 kyr; related to g_4-g_5 and g_4-g_2) and climatic precession (~19–23 kyr),

272   respectively. The S_{4a} and S_{4b} components then correspond to the ~23-kyr (k+g_5

273   and k+g_2) and ~19-kyr (k+g_4 and k+g_3) terms of the precessional index,

274   respectively (where k refers to Earth's precession rate, and g_2 through g_5 are the

275   secular frequencies of planetary motion; Berger and Loutre 1990). A signature of

276   axial obliquity (S_3) is relatively weak and localized; where present, its variance

277   never exceeds variance of the precessional signal (variance ratio <0.7).

278   The EHA signatures (IP in Figs. 4 and 5) suggest well-preserved

279   precessional and eccentricity signals throughout most of the Lower Turonian.

280   Above the Lower/Middle Turonian boundary, however, the astronomical signals

281   become less distinct at the J-719670 site. In addition, the lowermost Turonian of

282   J-719670 exhibits minor condensation spanning marker bed 9 and

283   corresponding to one S_4 (precessional) cycle (Fig. S1). To confirm and refine the

284   estimate of astronomical cyclicity in these intervals, additional boreholes are

285   examined.

286

4.1.2. Borehole J-650704, resistivity

287

288 This borehole is located approximately 4 km eastward of J-719670, closer to the

289 main siliciclastic depocenter of the Turonian depositional system (Fig. 2).

290 Proximity to the sediment source provides suitable conditions for the extension

291 of the S_4 signal into the Middle Turonian (Fig. 3). Spectral estimates for the

292 resistivity log reveal a pattern of S_2 and S_4 cyclicity, which is compatible with the

293 results for borehole J-719670 (Fig. 5).

294

4.1.3. Borehole 4523-A, greyscale

295

296 Borehole 4523-A Sedlec is located down the depositional dip relative to

297 boreholes J-719670 and J-650704 (Fig. 2). Type B cyclicity, which consists

298 primarily of sand/mud alternations (Figs. S7, S8), is less well expressed in this

299 distal area due to reduced textural variability and local winnowing. However,

300 unlike resistivity logs of J-719670 and J-650704, the high-resolution greyscale

301 record of 4323-A makes it possible to resolve the S_4 signal in carbonate-rich

302 facies surrounding the C/T boundary (Fig. 6).

303

4.2. Eccentricity phasing

304

305 The initial information on the phasing of ~100-kyr and 405-kyr eccentricity

306 cycles is obtained from bandpassed resistivity logs following removal of a linear

307 trend in sedimentation rate (Fig. 5). The bandpassed proxy, however, does not

308 bear any information on the polarity of the astronomical term. To estimate the

309 phase of the filtered proxy relative to the phase of the eccentricity forcing, we

310 employ a suit of additional indices including (i) amplitude modulation of

311   bandpassed precessional signal (see section 4.2.1), and (ii) preservation of

312   interference patterns of the precessional signals in depth-frequency plots.

313   Details on the interpretation are given below.

314

315   *4.2.1. Short eccentricity (~100-kyr)*

316   The inherent role of orbital eccentricity (e) in the climatic impact of axial

317   precession, quantified by the precessional index (e sinω, where ω is the

318   longitude of the perihelion from the moving equinox), results in an eccentricity-

319   paced modulation of the amplitude of precessional signals (e.g., Berger and

320   Loutre 1991). This amplitude modulation has therefore been acknowledged as a

321   tool to identify eccentricity maxima and minima (e.g., Herbert 1992; Grippo et al.

322   2004; Zeebe et al. 2017; Laurin et al. 2017). Any signals filtered from geological

323   data are, however, prone to distortion due to sedimentation-rate instabilities and

324   introduction of noise (both natural and analytical) into the filtered bandwidth.

325   An accurate extraction of amplitude-modulated signals from stratigraphic data

326   involves additional challenges such as frequency leakage out of the filtered

327   bandwidth or introduction of harmonic tones into the filtered bandwidth due to

328   short-term fluctuations in accumulation rates, diagenesis or differential

329   compaction. The use of amplitude modulation therefore requires additional

330   support. Here, the integrity of the precessional envelope is evaluated using

331   interference patterns in EHA plot, analogous to the evaluation of 400-kyr phase

332   in a previous study (Laurin et al. 2016).

333   The composition of fundamental frequencies of the main terms of short-

334   eccentricity (g_4-g_2 and g_4-g_5) and precessional index ($k+g_5$, $k+g_2$, $k+g_4$ and $k+g_3$;

335   Berger and Loutre 1990) links the interference of precessional terms to the

336   eccentricity phase, i.e., $(k+g_4)-(k+g_2) = g_4-g_2$, and $(k+g_4)-(k+g_5) = g_4-g_5$. As

337   illustrated in Figure 5c, intervals of constructive interference of the ~19-kyr and

338   ~23-kyr terms mark short-eccentricity maxima, and intervals of destructive

339   interference are aligned with short-eccentricity minima. These patterns can be

340   examined in EHA plots that also make it possible to identify non-stationarities

341   and determine noise levels in the precessional band (see Laurin et al. 2016 for

342   illustration of possible modes of signal distortion and their EHA signatures).

343   In the resistivity log of J-719670, the interference patterns are well

344   preserved between correlation markers 10 and 37 (Fig. 4) suggesting that the

345   precessional signal and its amplitude modulation are not severely distorted in

346   this interval. The precessional envelope in J-719670 can also be extended some

347   distance beneath a minor hiatus near marker bed 9. The J-650704 record is

348   noisier, but exhibits interference patterns that are consistent with those in J-

349   719670 (Fig. 5). The amplitude envelope of S_4 signal in J-719670 is therefore

350   used in this study as the primary tool for the interpretation of short-eccentricity

351   maxima and minima. For intervals lacking a robust precessional modulation,

352   such as the Cenomanian/Turonian boundary interval, the short eccentricity

353   phases are estimated from a filtered S_2 signal, the polarity of which is confirmed

354   with the TimeOpt analysis (Figs. S10 and S11).

355   It should be noted that the above approach cannot resolve minor phase

356   differences and deformations that are to be expected in this depositional setting.

357   However, the method of astrochronological tuning applied here (section 4.4) is

358   not sensitive to minor lead/lag differences in the precessional and eccentricity

359   records; the phasing uncertainty is accommodated by the total uncertainty of the

360   age model.

361

4.2.2. Long eccentricity (405-kyr)

The 405-kyr cycle, the rhythm of which is represented by signal S_1 (Fig. 4d), is part of the same astronomical forcing as the ~100-kyr eccentricity term. The preservation of its polarity should therefore be analogous to the preservation of short-eccentricity phasing inferred in section 4.2.1. This means that maxima in the filtered resistivity log should *approximate* the maxima in the original signal (as noted above, minor phase uncertainties are accommodated by the tuning approach). If so, then 405-kyr maxima should be located near marker beds 2a, 20 and 36 (Fig. 5). Support for this assumption can be sought in the modulation of precessional and short-eccentricity signals.

As with the short-eccentricity phasing, the phase of 405-kyr eccentricity (g_2-g_5) is involved in the interference of precessional terms. In this case, however, the interpretation in real stratigraphic data would require an exceptionally clear signal permitting separation of the 23.05-kyr $(k+g_5)$ and ~21.81-kyr $(k+g_2)$ precessional terms (Tab. S2a). In spite of an excellent signal preservation, these components cannot be resolved in the study interval. Other indices are therefore required.

Pronounced amplitude modulation and well-developed interference patterns in the precessional band can be expected to form preferably during 405-kyr maxima, as in the theoretical solutions. The nodes in 405-kyr eccentricity, in contrast, should exhibit relatively weak precessional signals and indistinct interference patterns in time-frequency plots (Fig. 5c). Following these assumptions, 405-kyr maxima should be centered between marker beds 17 – 21 and near markers 36 – 37, in agreement with the S_1 bandpass (Fig. 5a,b). This

386   interpretation is further supported by a transient record of eccentricity in the

387   Lower/Middle Turonian boundary interval in borehole Bch-1 (central part of the

388   basin; Figs. 7a and S12).

389   Modulation of the short-eccentricity signal (S_2) is of limited use due to an

390   upward decline in its power. Gradual facies change above marker bed 2b (Fig.

391   S7) and local winnowing of marker bed 9 (Fig. 5) also corrupt the S_1 bandpass in

392   the lower part of the study interval. To preserve a realistic, ~1:4 bundling of

393   short-eccentricity vs. long-eccentricity cycles, the lowermost maximum of the

394   405-kyr eccentricity should be located some distance above the lowermost

395   maximum of the S_1 bandpass, between markers 2b and 3 (between short-

396   eccentricity maxima ecc2 and ecc3; Figs. 5 and 7).

397   The final support for the interpretation of 405-kyr phase comes from

398   bundling ratios of short-eccentricity vs. precessional cycles that are controlled

399   chiefly by changes in the instantaneous period of short-eccentricity cycles. The

400   405-kyr minima are typically associated with low instantaneous periods (as low

401   as 77 kyr; Hinnov 2000) and low bundling ratios (as low as 1:3 during ~2.4-Myr

402   nodes). In the study interval, the bundling ratios range from 3.5 to 5.7 with

403   minima near marker beds 7 and 31, coincident with 405-kyr minima predicted

404   by the S_1 bandpass and precessional interference patterns (Fig. 7).

405

406   **4.3. Myr-scale eccentricity**

407   The ~2.4-Myr modulation of orbital eccentricity related to the precession of

408   perihelia of Earth and Mars ($g_4 – g_3$; Laskar et al. 2004) cannot be interpreted

409   directly due to a relatively short time span of the study interval (~1 Myr).

410   However, since long-term eccentricity minima exhibit suppressed ~100-kyr

411 modulations (Fig. 5c; cf. Hinnov 2000), the exquisite preservation of ~100-kyr

412 interference patterns in the middle part of the Lower Turonian and lower part of

413 the Middle Turonian makes it possible to infer a broadly defined ~2.4-Myr

414 maximum in this interval. Such a phasing implies a ~2.4-Myr node overlapping

415 with OAE II, in agreement with the results of previous studies (Batenburg et al.

416 2016; Laurin et al. 2016; Ma et al. 2019).

417

418 **4.4 Age model**

419 The study interval spans twelve short-eccentricity cycles labelled ecc1 through

420 ecc11 (a minor cycle at 405-kyr minimum is labelled ecc3b; Fig. 7). These cycles,

421 combined with the precessional cyclicity, provide the basis for the construction

422 of floating age model. The key issue affecting accuracy of the age estimate is the

423 selection of tuning targets for the eccentricity and precessional signals. A

424 constant tuning target, e.g., 95 kyr for short eccentricity, can be considered

425 inaccurate, because the instantaneous period of this cycle varies significantly in

426 the course of 405-kyr and Myr-scale modulations (e.g., Hinnov 2000). Tuning to a

427 particular segment of an astronomical solution would settle this issue, but all

428 astronomical solutions available to date are unreliable in their prediction of Myr-

429 scale eccentricity modulation beyond ~55 Myr ago (Laskar et al. 2011a,b; Zeebe

430 2017; Zeebe and Lourens 2019). To estimate the uncertainty associated with

431 Myr-scale modulation, we select a 10-Myr interval of the solution La2010d

432 centered at 94 Myr ago (~C/T boundary) and tune the observed signals to every

433 compatible segment of the theoretical solution in this interval.

434 The tuning is performed by linking individual S_4 cycles with precessional

435 cycles of the La2010d solution (Laskar et al. 2011a) within the framework of

436   ~100-kyr (S_2) and 405-kyr (S_1) maxima and minima interpreted in section 4.2. In

437   this concept, the precessional cycles provide the temporal resolution and

438   eccentricity cycles provide stability (by, for example, identifying missing

439   precessional beats at eccentricity minima). Each tuning assigns floating ages to

440   correlation markers 1 through 43, which are manifestations of the precessional

441   (S_4) cyclicity (Figs. S14 and S15). The mean and standard deviation of the

442   floating ages, calculated from the total number of tuned segments (n=21),

443   constitute the nominal age model and uncertainty of the tuning target (Tab. S3).

444   An interpolation of the nominal age model to chronostratigraphic

445   boundaries using the Bayesian approach (Bchron; Haslett and Parnell 2008)

446   suggests an 885 kyr duration for the Early Turonian. The uncertainty of this time

447   span is estimated as ±46 kyr (95% confidence interval) by combining the

448   uncertainty of the location of chronostratigraphic boundaries (Fig. 3) and the

449   uncertainty of the La2010d tuning target (Tab. 2). The age model makes it

450   possible to define the mean floating ages and uncertainties for the ~100-kyr and

451   405-kyr maxima and minima (Fig. 8): the Cenomanian/Turonian boundary

452   predates the nearest 405-kyr maximum by 81 ±32 kyr, and the Lower/Middle

453   Turonian boundary coincides with another 405-kyr maximum within the

454   uncertainty of ±33 kyr.

455

456   **4.5 Age-calibrated $\delta^{13}C$**

457   The Bayesian interpolation is further applied to estimate floating ages of carbon-

458   isotope samples in borehole 4523-A (Fig. 8). This age calibration suggests that

459   the negative shift in $\delta^{13}C$ following OAE II is superimposed upon increasing 405-

460   kyr eccentricity. The temporal distribution of small-scale anomalies

461 approximates a ~110-kyr pacing in the lowermost Turonian, but passes to a

462 longer, ~170-kyr pattern towards the Middle Turonian (Fig. 8d).

463

464 **5. DISCUSSION**

465 **5.1 Chronology of the Early Turonian**

466 The floating-age estimate presented here falls within the range presented in

467 previous studies (Tab. 1). It is most closely compatible with astrochronology of

468 the Wunstorf core (Voigt et al. 2008), with which it shares the precession-scale

469 resolution. The minor difference in the duration of Early Turonian (~40 kyr)

470 between these models might be related to the selection of monochromatic

471 precessional tuning target (21 kyr) and the loss of precessional signal in the

472 uppermost part of the Lower Turonian at Wunstorf. Another robust estimate, the

473 Portland time scale of Meyers et al. (2001, 2012a) and Sageman et al. (2006),

474 appears ~100 kyr short compared to the Bohemian model. The difference is

475 again possibly related to the use of a monochromatic tuning target, in this case

476 the 95 kyr for short eccentricity in Portland (note that the use of mean short-

477 eccentricity period of 110 kyr would increase the duration estimate by 16%,

478 matching the Bohemian estimate within its uncertainty). Other published

479 astrochronologies are difficult to assess due uncertainties in the definition of

480 chronostratigraphic boundaries in the Bottaccione (Sprovieri et al. 2013),

481 Contessa (Batenburg et al. 2016) and Iona (Eldrett et al. 2015) records.

482

483 **5.2 Eccentricity phasing across OAE II**

484 The inferred ~2.4-Myr node in eccentricity modulation during OAE II and a long-

485 term increase in the eccentricity amplitudes towards the Middle Turonian are in

486 agreement with previous results supporting the role of increasing seasonality in

487 the recovery from OAE II (Batenburg et al. 2016; Laurin et al. 2016). The 405-kyr

488 phasing, in contrast, cannot be compared directly with previous studies due to

489 uncertainties in stratigraphic correlation to published sections (Figs. 1 and S17)

490 and a lack of direct phase constraints across OAE II. Well-preserved astronomical

491 signals allowing a robust interpretation of the 405-kyr phases have been

492 described from the pre-OAE II interval at Furlo (Batenburg et al. 2016; Laurin et

493 al. 2016). When extrapolating eccentricity cycles of the Bohemian record to the

494 base of OAE II using published astrochronologies (Sageman et al. 2006; Ma et al.

495 2014; Fig. S13), the 405-kyr maxima appear ~90 kyr (80°) out-of-phase relative

496 to the Furlo record (Fig. 8c). Considering that both the Early Turonian and pre-

497 OAE II eccentricity records are robust, the most likely source of error is in the

498 extrapolation across OAE II. Possible explanations of the misfit include non-

499 deposition or condensation near the base of Livello Bonarelli at Furlo, or a minor

500 underestimation of the period of the eccentricity tuning target in the OAE II

501 chronology (since the 95 kyr target used in the Portland astrochronology is at

502 the low range of eccentricity periods; see also section 5.1).

503   Another apparent misfit is found in the Early Turonian, when comparing

504 the Bohemian 405-kyr record with eccentricity maxima inferred for the Contessa

505 section (Batenburg et al. 2016; Figs. 1f and S17). The two records can, however,

506 be aligned with each other when considering a ±150 kyr uncertainty for the

507 Contessa section (Batenburg et al. 2016) and delineating the

508 Cenomanian/Turonian boundary as in Wendler (2013) (Fig. S17).

509

510 **5.3 Short-term δ^{13}C anomalies: interbasinal correlation**

511   To facilitate the comparison of different records, we offer a simple adjustment of

512   the English Chalk and Portland δ^{13}C curves based on linear interpolation

513   between the C/T boundary and the newly proposed floating age of the

514   Lower/Middle Turonian boundary (Fig. 8). This simplified approach suggests

515   that the Holywell CIE (Jarvis et al. 2006) postdates the C/T boundary by 300-400

516   kyr and might be correlative to the excursion Tu2 or a minor anomaly above Tu1

517   at Wunstorf (supported by the first occurrence of *M. nodosoides* immediately

518   above Tu2; Fig. 8; cf. Voigt et al. 2008). In the Bohemian Cretaceous Basin, the

519   most likely candidate for the Holywell CIE is the excursion "se-10".

520   In general, a correlation of small-scale CIEs that lack a distinct structure

521   or magnitude will remain ambiguous without biostratigraphic constraints or

522   detailed age calibration of both the reference section and the correlated section.

523   The original depth-domain profiles and time-domain profiles interpolated across

524   large intervals can provide misleading information about the relative spacing of

525   CIEs due to unrecognized changes in sedimentation rates and distorted age-

526   depth relationships.

527

528   **5.4 Short-term δ^{13}C anomalies: timing and origin**

529   The ~100-kyr recurrence interval of short-term δ^{13}C anomalies in the earliest

530   Turonian (Fig. 8) points to the possible influence of eccentricity-modulated

531   seasonal insolation intensities on the carbon-cycle budget (cf. Berger et al. 1993).

532   The δ^{13}C signature is, however, not strictly coherent with inferred short-

533   eccentricity cycles (Fig. 6) suggesting a causal mechanism different from that

534   proposed for other greenhouse intervals, e.g., Paleocene-Eocene (Cramer et al.

535   2003; Zeebe et al. 2017). The observed incoherency may point to the

536   heterogeneous composition of carbon sources and sinks, involving sensitivity to

537   different aspects of the insolation control (e.g., seasonal intensity vs. integrated

538   seasonal insolation) and geographic locations. The possible role of high- or mid-

539   latitude carbon reservoirs responding to meridional insolation gradients (cf.

540   Raymo and Nisancioglu 2003) or integrated summer insolation (cf. Huybers

541   2006) is apparent in the transition towards ~170-kyr pacing of $\delta^{13}C$ anomalies in

542   the mid Early Turonian (Fig. 8d). The ~170-kyr term occurs in amplitude

543   modulation of axial obliquity (Hinnov 2000; Fig. S16) and its record in the

544   isotopic balance of the carbon cycle can be amplified by the ~100-kyr residence

545   time of carbon (Kump and Arthur 1999), analogous to the amplification of

546   eccentricity terms from precessional modulation (e.g., Short et al. 1991; Herbert

547   1997).

548   Notably, the transition from short-eccentricity pacing to ~170-kyr pacing

549   is superimposed upon the rising phase of long-term eccentricity modulation

550   (Figs. 5 and 8b). The loss of eccentricity pacing of $\delta^{13}C$ excursions can therefore

551   not be attributed to the inherent change in eccentricity amplitudes. To produce

552   the observed pattern, the carbon-cycle perturbations must have decoupled from

553   low-latitude seasonal insolation involving carbon storage in the monsoonal belt

554   (cf. Rossignol-Stricks 1983). The lead control on carbon-isotope mass balance

555   was transferred to mid- to high-latitudes during this interval, paralleling a Myr-

556   scale, obliquity-paced carbon exchange inferred in previous studies (Wendler et

557   al. 2014; Laurin et al. 2015) and the onset of long-term cooling of surface

558   temperatures (cf. Pucéat et al. 2003; Friedrich et al. 2012).

559

560   **SUMMARY**

1. The record of precessional and eccentricity cycles in the Bohemian
   Cretaceous Basin constrains the duration of Early Turonian to 885 ±46
   kyr.

2. The Cenomanian/Turonian boundary precedes the nearest 405-kyr
   maximum by 81 ±32 kyr. The recovery from OAE II is superimposed upon
   rising phases of 405-kyr and ~2.4-Myr eccentricity. The ~2.4-Myr cycle
   peaks between late Early Turonian and early Middle Turonian.

3. Astronomical control on the post-OAE II carbon cycle is documented by
   ~110-kyr pacing of δ^{13}C anomalies, which gives way to ~170-kyr
   obliquity pattern during the mid Early Turonian. The transition suggests
   decoupling of the carbon-cycle mass balance from low-latitude seasonal
   insolation and increasing role of high latitude carbon reservoirs.

4. The temporal and phasing constraints presented in this study can
   facilitate evaluation of short-term climate controls during peak
   greenhouse conditions.

589 **DATA AVAILABILITY**

590 Data discussed in this paper are provided in the Supplementary Information,

591 Datasets S1 through S5. By the time this article is accepted for publication, all

592 data will be deposited in the Pangaea Data Publisher.

FIGURE CAPTIONS

819

820 **Table 1.** Comparison of published age estimates for the Early Turonian. CIE =

821 carbon-isotope excursion; n.d. = not defined explicitly.

822

823 **Table 2.** Age calibration of chronostratigraphic boundaries and carbon-isotope

824 excursions (CIE) in reference boreholes. C.w. = *Collignoniceras woollgari*. CI =

825 confidence interval.

826

827 **Figure 1.** Overview of chronology (GTS2012; Gradstein et al. 2012) and carbon-

828 isotope stratigraphy of the study interval. Major carbon-isotope anomalies (CIEs)

829 are highlighted by blue shading (positive anomalies) and yellow shading

830 (negative anomalies). The Lower/Middle Turonian boundary is defined by the

831 first occurrence (FO) of *Collignoniceras woollgari*, which is

832 penecontemporaneous with the Lulworth CIE (Jarvis et al. 2006). **(a)** English

833 Chalk reference curve; modified after Jarvis et al. (2006); age calibration after

834 Pearce et al. (2020). **(b)** Borehole Bch-1, Bohemian Cretaceous Basin (Uličný et

835 al. 2014; Jarvis et al. 2015). **(c)** USGS #1 Portland core, Western Interior Basin;

836 lower part (black) after Sageman et al. 2006 ("min option" in their fig. 1); upper

837 part (blue) after Joo and Sageman (2014). **(d)** Wunstorf core, age calibrated

838 (floating astrochronology after Voigt et al. 2008). **(e)** Contessa section plotted in

839 the depth domain (Stoll and Schrag 2000). **(f)** Eccentricity maxima interpreted

840 by Batenburg et al. (2016).

841

842 **Figure 2.** Paleogeographic context. **(a)** Plate tectonic reconstruction after Hay et

843 al. (1999). Land/sea distribution is simplified after the PALEOMAP Project, C.R.

844 Scotese (www.scotese.com). BCB = the Bohemian Cretaceous Basin. **(b)** Detail of

845 the study area (modified after Uličný et al. 2009, 2014) plotted in the present-

846 day coordinate system.

847

848 **Figure 3.** Reference boreholes and data discussed in this study. Numbers 1a

849 through 46 denote correlation markers (see Figs. S1-S6 for a detailed correlation

850 and Figs. S7-S8 for lithology). Carbon isotope excursions in the Lower Turonian

851 are labelled "se-20", "be-20", etc., where "se" and "be" refer to the location

852 (Sedlec and Beřkovice, respectively). Grey shading highlights the Oceanic Anoxic

853 Event II (OAE II). GR = gamma ray, RES = resistivity, XNN = neutron-neutron log.

854 Blue shading marks the correlation uncertainty of the Cenomanian-Turonian and

855 Lower-Middle Turonian boundaries (Figs. S1-S6 and S13). Type A cycles =

856 carbonate-dominated lithofacies; Type B = siliciclastic-dominated lithofacies

857 (Figs. S7 and S8). Lithostratigraphy after Čech et al. (1980). Genetic sequences

858 after Uličný et al. (2009). Wavy line = omission surface.

859

860 **Figure 4**. Spectral estimates, borehole J-719670. **(a)** Resistivity log (RES). Labels

861 1a through 45 denote correlation markers most of which correspond to maxima

862 in the S_4 signal. **(b)** MTM (3 2π) amplitude estimate for the common logarithm of

863 RES obtained with a 7-m moving window (EHA). F-test significance estimates are

864 presented in Fig. S9. Potential signals are labelled S_1 through S_4. Interference

865 patterns (IP) are highlighted by arches ")". Note that the amplitude and F-test

866 maxima corresponding to the S_4 signal migrate towards lower frequencies

867   paralleling an upward increase in sand contents and a large-scale progradational

868   pattern in the coeval siliciclastic system (Fig. S1). The EHA pattern resembles a

869   reciprocal function of signal wavelength, consistent with a linear increase in

870   sedimentation rate. **(c)** Resistivity log and EHA amplitude after removal of the

871   linear trend. Intervals of constructive interference of S_{4a} and S_{4b} signals (x)

872   delineate ~100-kyr eccentricity maxima. **(d)** MTM and ASM results for the

873   interval 380-418m. The ASM analysis is based on all F-test maxima exceeding the

874   0.90 level between frequencies 0 and 5 cycle/m. Ho/SL = null-hypothesis

875   significance level. Sedimentation rates constrained by GTS2012 are shown by

876   ochre shading. Blue lines and symbols indicate the best fit to the astronomical

877   terms of long eccentricity (E_1; 405 kyr period), short eccentricity ($E_{2,3}$; 127 and

878   97 kyr periods), obliquity ($O_{1,2}$; 49 and 39 kyr periods) and precession (P_{1-4}; 23 -

879   19 kyr periods; Tab. S2a).

880

881   **Figure 5**. Correlation of astronomical signals. **(a, b)** Astronomical signatures in

882   boreholes J-719670 and J-650704; setup as in Fig. 4. Intervals of constructive

883   interference of the S_{4a} and S_{4b} signals (x) delineate ~100-kyr eccentricity

884   maxima. Series of strong interference patterns (IP) in the EHA plot mark 405-kyr

885   maxima (ochre shading) superimposed upon a maximum in ~2.4-Myr

886   modulation (cf. Fig. 5c). Note that the fidelity of S_4 envelopes and polarity of S_1

887   (405-kyr) signals would remain uncertain without IP (cf. Laurin et al. 2016). **(c)**

888   Comparison with the astronomical solution La2010d (Laskar et al. 2011a); the

889   nearest interval compatible with eccentricity phasing in the study interval. Filter

890   setup (Taner, roll-off rate 4×10^4): J-719670, S_4 = 1.00±0.30 cycle/m, S_2 =

891   0.20±0.05 cycle/m, S_1 = 0.05±0.01 cycle/m; J-650704, S_4 = 1.15±0.35 cycle/m, S_2

892   = 0.23±0.05 cycle/m, S_1 = 0.05±0.01 cycle/m; La2010d, prec. = 50±15 cycle/Myr,

893   short ecc. = 10±3 cycle/Myr, long ecc. = 2.47±0.5 cycle/Myr.

894

895   **Figure 6.** Interpretation of astronomical signatures, borehole 4523-A. **(a)**

896   Carbon-isotope data, greyscale and filtered signals. Filter setup (Taner, roll-off

897   rate 4×10^4): S_4 = 1.00±0.30 cycle/m, S_2 = 0.23±0.05 cycle/m. **(b)** EHA spectral

898   estimate for greyscale data; dashed lines denote the expected trace of the S_4

899   (precessional) signal inferred from correlation to borehole J-719670 (5-m

900   moving average). **(c)** MTM and ASM estimates for greyscale data, interval 190-

901   203 m. See Tables S2a and S2b for ASM setup. Sedimentation rates constrained

902   by GTS2012 are shown by ochre shading.

903

904   **Figure 7.** Eccentricity framework constraining the tuning target (see also Figs.

905   S14 and S15). **(a-d)** Filtered precessional and eccentricity signals in reference

906   boreholes. Maxima in short-eccentricity cycles (~100 kyr; labelled ecc1 through

907   ecc11) are inferred using a combination of bandpassed S_2 and amplitude

908   envelopes of the precessional signal (S_4): in the middle and upper parts of the

909   succession that exhibit distinct precessional modulations (Fig. 5), the ~100-kyr

910   maxima are based primarily on amplitude envelopes of the S_4 signal in borehole

911   J-719670; the lower part of the succession exhibits less stable precessional

912   signals; ~100-kyr maxima ecc1-ecc3 are therefore placed at maxima in the S_2

913   bandpass (see text). Long-eccentricity, 405-kyr, maxima (ochre shading) are

914   placed at intervals with strong precessional interference patterns (Figs. 4 and 5).

915   **(e)** Bundling ratios of precessional (P) vs. short-eccentricity (E) signals in the

916   study interval. **(f)** Correlation to the nearest compatible segments of the

917 astronomical solutions La2010d (Laskar et al. 2011a) and La2004 (Laskar et al.

918 2004). Filter setup (Taner, roll-off rate 4×10^4): Bch-1, S_2 = 0.15±0.04 cycle/m;

919 4523-A, S_4 = 1.00±0.30 cycle/m, S_2 = 0.23±0.05 cycle/m, S_1 = 0.05±0.01 cycle/m;

920 J-719670, S_4 = 1.00±0.30 cycle/m, S_2 = 0.20±0.05 cycle/m, S_1 = 0.05±0.01

921 cycle/m; J-650704, S_4 = 1.15±0.35 cycle/m, S_2 = 0.23±0.05 cycle/m, S_1 =

922 0.05±0.01 cycle/m; La2004 and La2010d, prec. = 50±15 cycle/Myr, short ecc. =

923 10±3 cycle/Myr, long ecc. = 2.47±0.5 cycle/Myr.

924

925 **Figure 8.** Updated chronology and eccentricity phasing for the Early Turonian.

926 **(a)** Chronology; duration of the Early Turonian is estimated as 885 ±46 kyr (Tab.

927 2); the floating astrochronology is anchored to the GTS2012 age of the C/T

928 bondary (93.9 ±0.15 Myr ago). Duration of the Cenomanian part of OAE II

929 (shaded) is based on Sageman et al. (2006) and Ma et al. (2014); Fig. S13. **(b)** The

930 nearest segment of the astronomical solution La2010d (Laskar et al. 2011a)

931 whose eccentricity phasing is compatible with eccentricity signatures in the

932 study interval (Figs. 4, 5 and 7). Filter setup as in Figure 7. Well-preserved

933 modulation in the middle and upper parts of the study interval suggests that

934 these intervals overlap with a ~2.4-Myr eccentricity maximum. If so, then OAE II

935 coincides with a node in the 2.4-Myr cycle, in agreement with previous results

936 (Batenburg et al. 2016; Laurin et al. 2016). **(c)** Timing of 405-kyr eccentricity

937 maxima (ochre shading) and minima inferred in this study. Comparison with

938 eccentricity phasing at Furlo (Italy) is shown at the bottom; IRM = Isothermal

939 Remanent Magnetization; black = sum of eccentricity components; red = 405 kyr

940 (Laurin et al. 2016). **(d)** EHA estimate for age-calibrated $\delta^{13}C_{org}$, borehole 4523-A.

941 **(e)** Age-calibrated carbon-isotope curves. The Early Turonian interval of 4523-A

942   is calibrated in high-resolution as described in sections 4.4 and 4.5. A linear

943   sedimentation rate of 1.55 cm/kyr is applied to the Cenomanian segment of

944   4523-A, beneath marker 1a (grey part of δ^{13}C curve; Fig. S13). Local isotope

945   excursions are indicated ("se-6", etc.). Age calibration of the Wunstorf record is

946   adopted from Voigt et al. (2008). English Chalk (Jarvis et al. 2006; Pearce et al.

947   2020) and Portland (black: Sageman et al. 2006; blue: Joo and Sageman 2014)

948   records are recalibrated in the time domain by linearly adjusting the duration of

949   the Early Turonian. Abbreviations: *I.c. = Inoceramus cuvieri, C.w. = Collignoniceras*

950   *woollgari, M.n. = Mammites nodosoides, M.pu. = Mytiloides puebloensis, W.d. =*

951   *Watinoceras devonense, M.g. = Metoicoceras geslinianum.*

Voigt et al. (2008)	Wunstorf	0.84	n.d.	Precession-scale resolution; robust astronomical signature	Precession-paced chronology does not reach the top of Early Turonian; modulation of the tuning target not considered
Gradstein et al. 2012 (GTS 2012)		1.0	n.d.		Meyers et al. (2012a) misquoted [1]); Voigt et al. (2008) not considered
Sprovieri et al. (2013)	Bottaccione	0.6-0.8	n.d.	Well-defined 405-kyr signature	No ammonite zonation; reduced resolution near C/T boundary
Eldrett et al. (2015; their fig. 11)	Iona	1.14	n.d.	High-resolution astronomical signature	No ammonite zonation; Early/Middle Turonian boundary placed deep into a major positive CIE (runup to Round Down CIE)
Batenburg et al. (2016)	Contessa	0.6-1.2	n.d.	Well-defined eccentricity signature	No ammonite zonation; C/T boundary controversial (cf. Wendler 2013; Fig. 1)
This study	Bohemian Cretaceous Basin	0.885	0.046	Precession-scale resolution; robust eccentricity phasing; modulation of the tuning target included in uncertainty	Biostratigraphy correlated from adjacent boreholes (correlation uncertainty acknowledged in the uncertainty range)

[1]) *The duration of W. devonense Zone is given as 0.35 Myr with reference to Meyers et al. (2012a); Meyers et al. (2012a), however, indicate ~0.2 Myr (two short-eccentricity cycles; their figure 1).*

La2004 age [Myr ago]

*) Filtered S₁ is probably biased by condensation at ecc3b (Fig. 4) and lithological change (Type A vs. Type B transition; Fig. S7); precession-scale correlation to the astronomical solutions suggests a 405-kyr maximum between ecc2 and ecc3, i.e., approximately one short-eccentricity cycle above the maximum in filtered S₂; the later timing preserves the 1:4 bundling of long- vs. short-eccentricity cycles.
